Mannan-binding protein/mannose-binding lectin (MBP/MBL) binds to terminal mannose groups on the surfaces of bacteria and enhances uptake by phagocytes through opsonization. Its structure is like that of C1q and, together with associated proteases, it can initiate the classical pathway in the absence of antibody. As it recognizes a broad range of infectious agents and is part of the early innate immune response, variation in this molecule may be critical in disease susceptibility (Fearon and Locksley 1996; Ezekowitz 1998). Polymorphisms in exon 1 of *MBL* (*MBL2*, chromosome 10q11.2-q21), at codons 52, 54, and 57, lead to low or absent serum MBL. The codon 54 mutation results in an unstable protein that is unable to activate complement. The effects of these mutations are detectable in the heterozygous state. As the frequency of these mutations is high, inevitably this has raised the question of selection. However, no selective advantage has been demonstrated to date (Ezekowitz 1998). There is also variation in the promoter region (Madsen et al. 1998). A number of population studies have attempted to correlate *MBL* haplotypes with varying concentrations of MBL in Old World and New World populations (Madsen et al. 1998; Turner et al. 2000; Boldt and Petzl-Erler 2002). The role of *MBL* variation in susceptibility to infectious disease has received considerable attention (Hill 1998).

The chromosome 5 gene cluster and other genes influencing IgE

The main stimulus for research into genetics of the 5q region has been its connection with the most common group of multifactorial disorders in western populations: asthma and atopy. Looking at linkages for asthma and atopy from the Asthma Gene database, chromosome 5 is most commonly identified (see www.cooke.gsf.de/asthmagen/main.cfm). For asthma/atopy, and latterly for infectious disease susceptibility, studies have concentrated on linkage rather than association. There are many reviews of the genetics of asthma and atopy available (Anderson and Cookson 1999). Genes present in the extended 5q31–q33 region include cytokine genes typically associated with a Th2 response: *IL3*, *IL4* (Arai et al. 1989), *IL5*, *IL9*, *IL13*, and also the gene coding for the p40 subunit of IL-12 (*IL12B*, Sieburth et al. 1992) (Figure 3). Other genes of interest include *IRF1* (interferon regulatory factor), *CSF2* (granulocyte–macrophage colony-stimulating factor (GM-CSF)), *CD14* (Goyert et al. 1988), *ADRB2* (β_2-adrenergic receptor), and *CSF1R*. A detailed physical map is available (Frazer et al. 1997). It appears there have been a number of gene duplication events, although some require rapid sequence divergence (van Leeuwen et al. 1989). New genes are being identified for asthma that may have direct links with infectious disease susceptibility. Identification of the *Tim* gene family in the region determining the *Tapr* locus (T-cell and airway phenotype regulator) used mice congenic for the chromosomal region homologous with human 5q23-q35 (McIntire et al. 2001).

The wealth of candidate immune response genes perhaps accounts for why studies either fail to develop beyond linkage approaches or are isolated gene association studies. There are a number of SNP and microsatellite polymorphisms in and between genes in this region (Noguchi et al. 2001). A few have been used extensively in study of disease, some of which are proposed to have functional consequences, such as the IL-13-coding polymorphism (Heinzmann et al. 2000). Where polymorphic sites are sufficiently dense haplotypes have been derived (Drysdale et al. 2000; Graves et al. 2000). Although linkage disequilibrium does occur in this region, unlike for HLA, there have been few attempts to characterize patterns (Takabayashi et al. 1999). There is a potential role of this gene cluster in regulation of Th1/Th2 responses, despite indications that the Th1 versus Th2 split is not controlled by *IL4* directly (Guler et al. 1999). Recent research has centered on control of the genes in this region, in particular the region between *IL4* and *IL13*. By comparing human and mouse sequences, a 401-bp-conserved noncoding sequence CNS-1 immediately downstream of *IL13* has been identified (Loots et al. 2000). Experiments in mice suggested this region as a coordinate regulator of *IL4*, *IL13*, and *IL5* spanning 120 kb. The capacity to develop Th2 cells was compromised in vitro and in vivo in the absence of CNS-1, despite retaining some capacity to produce IL-4 (Mohrs et al. 2001). Chromatin accessibility is likely to be important in cytokine expression (Agarwal et al. 1999; Hural et al. 2000; Guo et al. 2002).

Total IgE has been known to be under genetic control for many years with heritability estimates in excess of 50 percent (Bazaral et al. 1974; Blumenthal et al. 1981). Total IgE is perhaps the best characterized of the multiplicity of asthma/atopy traits. The best linkage known for control of a quantitative immune trait is the linkage of total IgE to the chromosome 5q31 gene cluster, first described by Marsh et al. (1994) in Amish sib-pairs. This linkage has been confirmed in a number of populations (Xu J. et al. 2000) and not detected in a few (Laitinen et al. 1997). In the context of total IgE, *IL4*, *IL13* (Graves et al. 2000; Liu et al. 2000), *CD14* (Baldini et al. 1999), and *ADRB2* (Dewar et al. 1997) have all been studied. There are sufficient data in the literature for meta-analysis, which will hopefully contribute to elucidation of which genes and how many genes are important for disease states in this region (Collins et al. 2000).

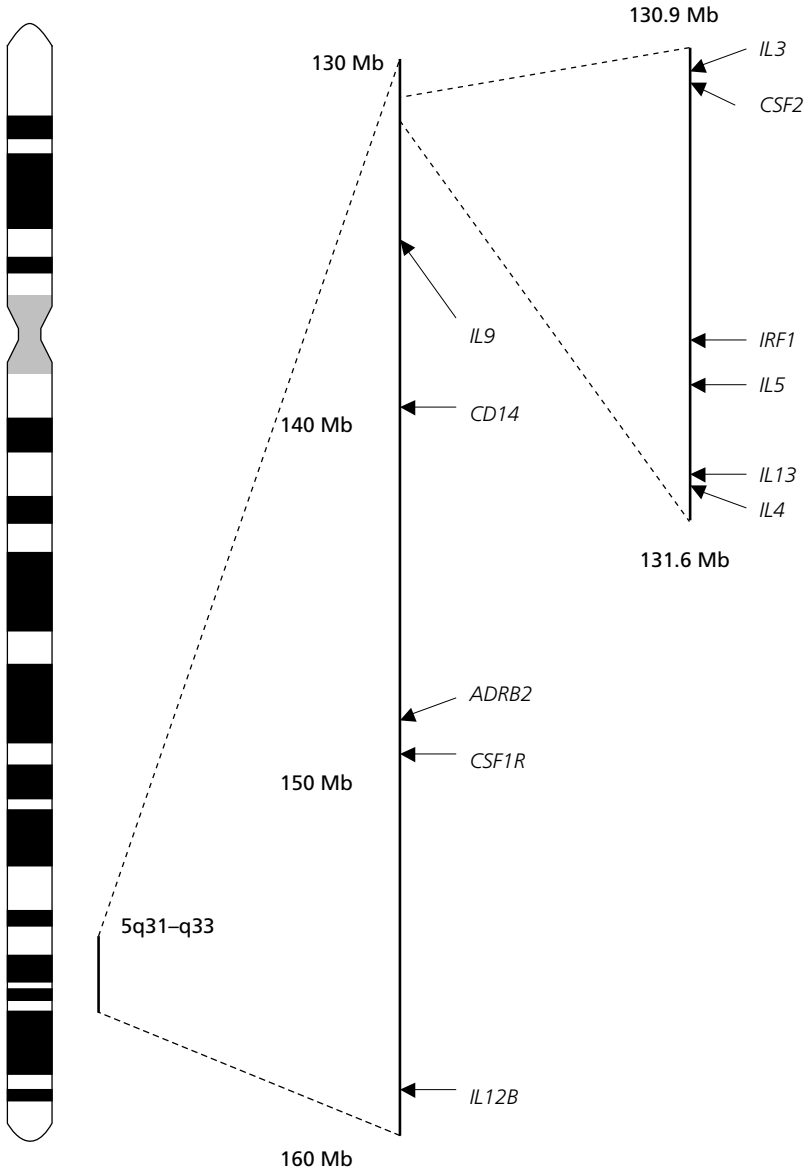

Figure 3 *The chromosome 5 gene cluster.*

The 5q cluster is also implicated in a number of inflammatory diseases some of which may have infectious disease etiology. A gene *IBD5* (inflammatory bowel disease 5) confers susceptibility to Crohn's disease and lies in 5q31. Use of a TDT approach gave strong evidence that a common 5q31 haplotype conferred susceptibility to Crohn's disease, although causal mutations remain to be identified (Rioux et al. 2001).

Familial eosinophilia is a rare autosomal dominant disorder. A genome scan provided evidence for linkage of this trait to chromosome 5q31–q35 (Rioux et al. 1998). There were no functional mutations in *IL3*, *IL5*, or *CSF2*, suggesting a defect elsewhere in this region. This may prove comparable to the *IFNGR1* story where there are both rare deleterious mutations and common less or nonpathogenic variants. The region proves to be of interest for helminth infections associated with IgE and eosinophilia.

Variation in receptors for the 5q-encoded cytokines is also implicated in asthma and atopy. The IL-4 and IL-13 receptors are inextricably linked through the sharing of a common IL-4Rα chain and overlapping specificities (IL-4 binding to both receptors) (Callard et al. 1996). The IL-4Rα chain has been extensively investigated in the context of asthma and atopy. There are a number of common coding polymorphisms known, of which the most studied are an extracellular variant Ile50Val (Mitsuyasu et al. 1998, 1999) and a cytoplasmic variant Gln576Arg (Hershey et al. 1997; Grimbacher et al. 1998; Wang et al. 1999). There is some evidence for a functional effect of each polymorphism: Arg576 was associated with increased expression of CD23 after IL-4

stimulation of mononuclear cells, and Ile50-transfected cells showed augmented responses to IL-4, which appeared not to change chain expression but to augment STAT6 activation. However, initial findings have not been entirely supported, and recent studies have suggested that variation at more than one site is necessary for functional effects, e.g. at both positions 50 and 576, or positions 503 and 576 (Kruse et al. 1999). Functional significance of variants within this gene remains topical. In addition, many associations have been reported between alleles at various positions, but with variation between studies. Analysis of *IL4RA* haplotypes has been of some value. The IL-4R story is a good example of confusion through examination of associations, and potential functionality of particular variants, in isolation. However, with more polymorphisms being identified, in both the promoter (Hackstein et al. 2001) and coding (Deichmann et al. 1997) regions, further consideration of haplotypes should prove informative (Risma et al. 2002). Using variants in both *IL13* and *IL4RA* there are early indicators of gene–gene interactions (Howard et al. 2001).

Variants in *IL12B* and receptors for Th1-type cytokines, have been studied primarily in the context of mycobacterial infection and are considered under the appropriate section.

A refined segregation analysis was compatible with more than one gene regulating total IgE (Xu et al. 1995). As total IgE is likely to be a multifactorial trait, a number of other genes have secondarily been implicated, which include *FCER1B*, *IL4RA*, *TNF*, loci on chromosomes 7 (Xu J. et al. 2000) and 12 (Barnes et al. 1996; Nickel et al. 1997; Xu J. et al. 2000), *INFGR1* and *IFNGR2* (Gao et al. 1999), and an *IL18R* splice variant (Watanabe et al. 2002). The gene for the β chain of the high-affinity IgE receptor, *FCER1B*, is on chromosome 11q13, and there is linkage of several asthma/atopy traits to this region in some populations. The original report was notable for its analysis of maternal transmission (Cookson et al. 1992). Three identified coding variants of *FCER1B* have shown some associations, but the precise effect of these polymorphisms is unclear (Furumoto et al. 2000; Hizawa et al. 2000). That results are somewhat mixed for Ile181Leu and Val183Leu, but less so for Glu237Gly, may be indicative of population heterogeneity. There have been very few attempts at haplotype construction across polymorphisms in this region. Other genes in this region, such as *CC16*, may be implicated. Together with the chromosome 5 cluster, 11q13 is the most investigated region in the context of asthma/atopy.

The chromosome 17 genes

Genes on the long arm of chromosome 17 have received less attention than the chromosome 5 cluster (Figures 4 and 30.5). However, with increasing interest in chemokines and chemokine receptors, largely stimulated by HIV-1 studies, and the occurrence of multiple candidate genes, it is likely that this region will prove critical in determining susceptibility to infectious disease.

Receiving the most attention to date is *NOS2A*, the gene coding for inducible nitric oxide (NO) synthase. There are three genes coding for nitric oxide synthase, but only the inducible form maps to this region (Marsden et al. 1994; Xu et al. 1994). As NO is a killing mechanism for intracellular macrophage bacteria and protozoa, a rate-limiting enzyme responsible for NO production is clearly important. Several variants in *NOS2A* have been widely investigated in relation to infectious disease susceptibility (Hobbs et al. 2002; Xu W. et al. 2000).

A number of small inducible cytokine genes named '*SCYA*', now renamed as chemokine CC motif ligand 'CCL', also occur in this region. One such molecule is the proinflammatory chemoattractant RANTES (*SCYA5*). Relatively late appearing mRNA transcripts are upregulated in cells stimulated with TNF-α and IL-1β, and TNF-α induces transcriptional activation of *SCYA5*, although regulatory mechanisms may be tissue-specific (Nelson et al. 1993). Also coded in this region are two related C-C chemokines macrophage inflammatory protein 1α(MIP-1α, *SCYA3*) and 1β (MIP-1β, *SCYA4*). The genes are 14 kb apart, arranged in a head-to-head fashion, in keeping with their coordinate regulation. In addition there are reduplicated loci in this region, the presence of which varies between individuals (Irving et al. 1990). Syntenic, but proximal to *SCYA3* and *SCYA4*, between the genes for RANTES and monocyte chemotactic protein-1 (MCP-1) (*SCYA2*), are the genes coding for MCP-2 (*SCYA8*) and MCP-3 (*SCYA7*) (Opdenakker et al. 1994). Breakpoints in the region are associated with several malignancies. It is reasonable to assume, as for C-X-C chemokine genes on chromosome 4q13–q21, C-X-C chemokine receptor genes on chromosome 2q34–q35, and C-C chemokine receptor genes on chromosome 3p21.3, that the origins of these molecules are through gene duplication. This is in keeping with repeat and palindromic sequences in the region (Opdenakker et al. 1994). Another locus in this cluster is eotaxin (*SCYA11*), also stimulated by TNF-α and IL-1α, with eosinophil-specific chemotactic ability and close homology to MCP-4 (*SCYA13*) (Bartels et al. 1996). As for the other genes in this cluster, eotaxin shows polymorphic variation (Miyamasu et al. 2001), in this case associated with plasma eotaxin levels and eosinophil counts, and may account for some of the genetic component proposed to determine eosinophil levels (Holberg et al. 1999).

Other polymorphisms

A number of other immune response genes have been proposed as candidates for resistance/susceptibility to

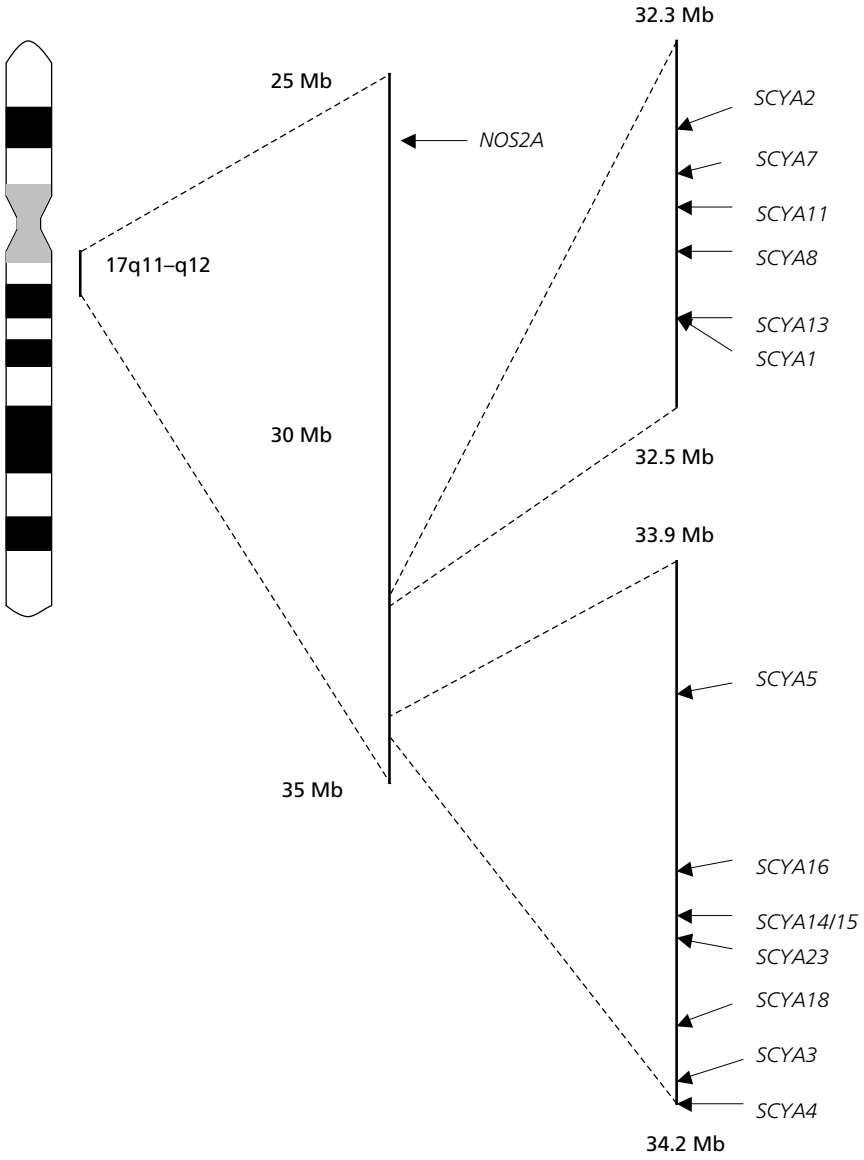

Figure 4 *Chromosome 17: genes on the long arm*

infectious disease, although the number of studies to date is limited. These include gene clusters coding for members of the Ig superfamily: Ig gene allotypes, T-cell receptor genes, and Fc receptor genes (including *CD32*) (Figure 6). However, the literature on T-cell receptor gene usage outweighs the information on polymorphic diversity. Such gene clusters do not display the high allelic diversity of the MHC. Among the cytokine genes most commonly investigated in an infectious disease context are those coding for IFN-γ (*IFNG*, 12q14), transforming growth factor β (TGF-β1) (*TGFB1*, 19q13), and IL-10 (*IL10*, 1q31–q32). Multiple polymorphic sites allow the construction of haplotypes. There has also been much interest in a variety of receptors, ligands, and adhesion molecules: CTLA-4 (*CTLA4*, 2q33), intercellular adhesion molecule 1 (ICAM-1) (*ICAM1*, 19p13), CD36 (*CD36*, 7q11), DARC (*FY*, 1q21–q22), and the vitamin D receptor (*VDR*, 12q12–q14). All of these, with the exception of *VDR*, have been studied primarily in the context of malaria. The active form of vitamin D is 1,25-dihydroxycholecalciferol, an immunomodulatory molecule, and the *VDR* gene has been considered for several infectious diseases.

Aside from the general web-based databases that catalogue microsatellite and single nucleotide polymorphisms, there are a few more specialized databases. Many of the polymorphisms that have been investigated for multifactorial diseases are in cytokine genes and have been collated (Bidwell et al. 1999a, b; Haukim et al. 2002). This specialist database has the advantage of providing detailed information on functionality and past disease associations. More generally, the On-line

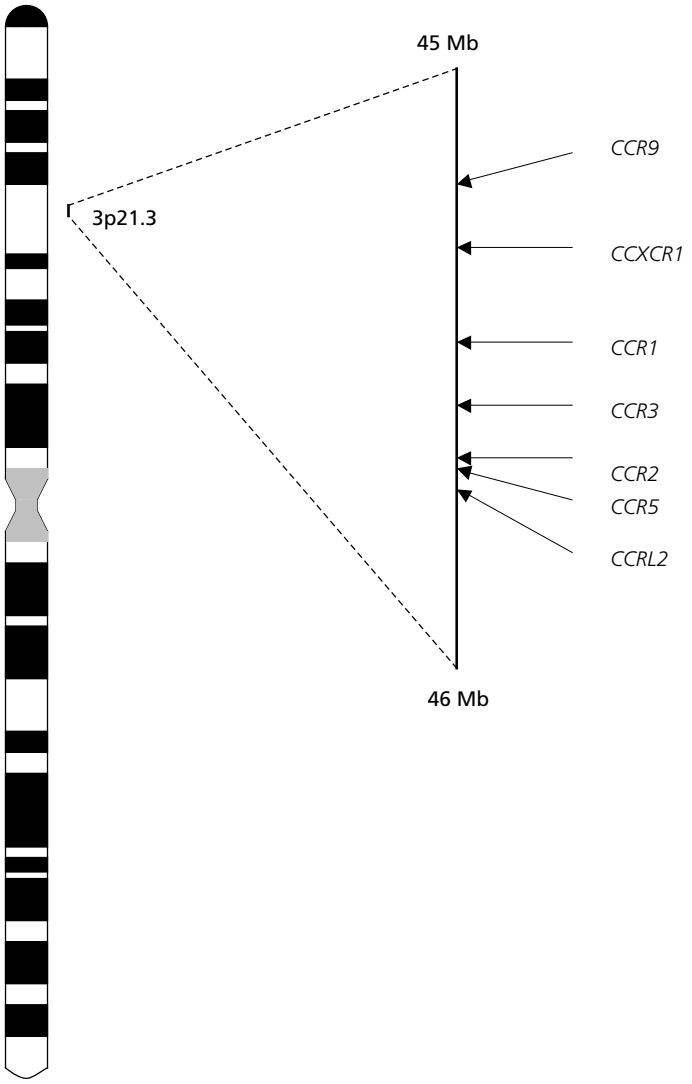

Figure 5 *Chromosome 17: genes on the short arm*

Mendelian Inheritance in Man (OMIM) site allows keyword searching and a history of genes and their variants. Whether polymorphisms are of functional relevance is a difficult issue. Clearly polymorphisms in regulatory regions may influence gene expression, and coding variation resulting in amino acid substitutions may affect function. Suffice it to say that there is very little good evidence of functional importance for most polymorphic sites.

Interestingly some cytokine genes, *IL2* and *IL4*, have been shown to be expressed monoallelically in single cells (Matesanz et al. 2000). This phenomenon of allelic exclusion is usually associated with the Ig molecules, where allelic exclusion is clearly necessary if a single cell is to produce a single Ig molecule. The reason for allelic exclusion in cytokine production is less clear. The mechanism appears to be through asynchronous DNA transcription (Mostolavsky et al. 2001).

VIRAL INFECTIONS

The number of human genetic studies on susceptibility to most viral infections is not high. This is surprising because receptor-mediated viral entry provides a number of good candidate genes. Studies are much farther forward in mice, although there are some limitations on simple extrapolation from mouse to humans (Brownstein 1998).

HIV

Human studies have concerned susceptibility to HIV-1 rather than HIV-2. There are a number of reviews available (Rowland-Jones 1998; Kaslow and McNicholl 1999; Michael 1999). Interest is focused in several areas: those individuals who remain seronegative despite

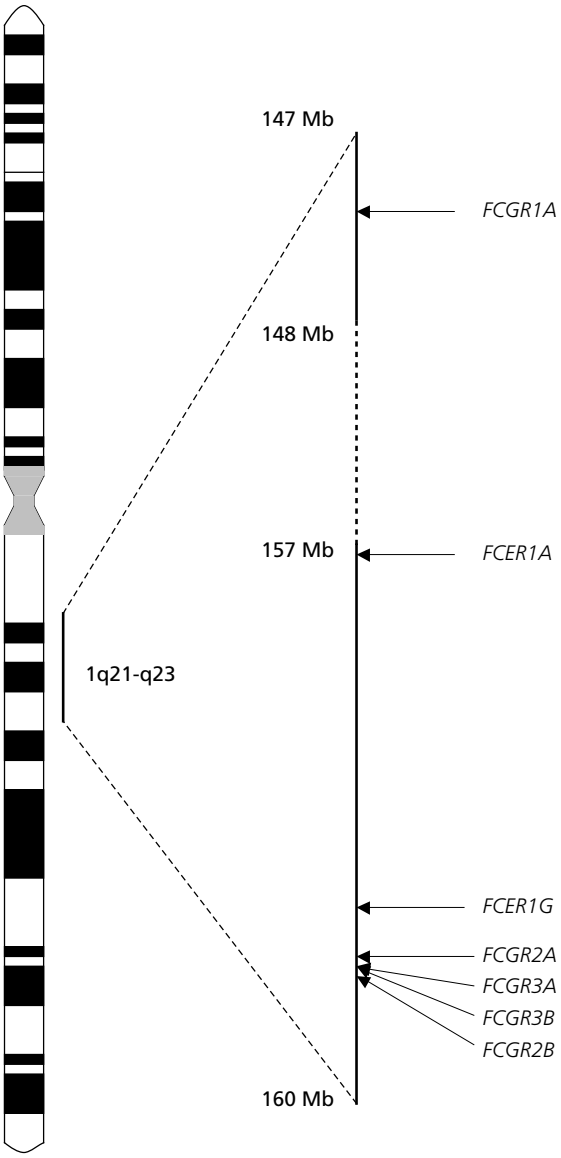

Figure 6 *Chromosome 1*

repeated exposure, differences in progression of disease after seroconversion, pediatric infection, and vertical transmission (Matte and Roger 2001), and latterly an interest in susceptibility to the various opportunistic infections. To a limited extent we now have the ability to collect genetic information from patients to give potential indicators as to disease progression (Carrington et al. 2001). HIV-1 uses co-receptors to enter host cells. The first co-receptor identified was CXCR4, then known as fusin, necessary for invasion of syncytium-inducing, T-cell-tropic isolates into $CD4^+$ T cells in the later stages of infection. Recombinant fusin enabled CD4-expressing nonhuman cells to support HIV-1 fusion. Antibodies to fusin blocked cell fusion and infection with normal $CD4^+$ human cells (Feng et al. 1996). CXCR4 is the receptor for stromal-derived factor 1 (SDF-1).

There is a greater literature concerning CCR5, rapidly implicated after CXCR4 (Deng et al. 1996; Dragic et al. 1996), as a necessary co-receptor for entry of nonsyncytium-inducing isolates into macrophages in the early stages of infection. Discovery was followed by description of the mechanism of entry: high-affinity binding of gp120 to CD4 causes conformational changes in gp120, creating a recognition site for CCR5 (Trkola et al. 1996; Wu et al. 1996). CCR5 is the receptor for the CC chemokines MIP-1α, MIP-1β, and RANTES, the genes of which have been studied in relation to HIV-1. Other members of this receptor family, CCR3 (the receptor for eotaxin) and CCR2b, have emerged as potential alternative co-receptors to CCR5.

Samson et al. (1996) showed that a variant 32-bp deletion in *CCR5* makes up about 10 percent of alleles in western Caucasian populations, but was absent from west and central African and Japanese populations. This leads to a truncated protein that is not functionally expressed (Liu et al. 1996). In HIV-infected Caucasians no homozygotes for *CCR5Δ32* were found, and the frequency of heterozygotes was 35 percent lower than in the general population. As primary infections were thought to be with nonsyncytium-inducing strains, initial observations suggested that such homozygotes would be totally refractory. Indeed cells from a homozygous individual were resistant to infection by macrophage tropic viruses. However, a handful of exceptions are now taken to be infection with syncytium-inducing or dual tropic strains utilizing CXCR4. Heterozygotes are not resistant but have slower disease progression, again protection being against nonsyncytium-inducing strains (Michael et al. 1997). Other mutations in *CCR5* occur with lower frequency and, although less is known of their effects, some produce functional alterations. Mutations within the *CCR5* promoter are likely to have less easily detectable effects than those resulting in truncated proteins. The ease with which mutations have been identified in *CCR5* argues for selective pressure favoring these alleles (Blanpain et al. 2000). The *CCR5Δ32*-containing ancestral haplotype has been estimated to be 700 years old, and this recent emergence is consistent with a strong selective event such as a plague epidemic (Stephens et al. 1998). CCR3 and CCR5 are both expressed in microglial cells of the central nervous system (CNS), and are thought to be responsible for transmission of macrophage tropic strains within the CNS (He et al. 1997). *CCR3* also shows several genetic variants (Zimmermann et al. 1998).

A mutation in the gene coding for CCR2b results in a conservative valine-to-isoleucine substitution at codon 64. Although described as affecting HIV progression, this gene is in linkage disequilibrium with *CCR5*, both being on chromosome 3 and only 20 kb apart.

Hence, for these mutations, causal effects can be hard to disentangle. Smith et al. (1997) showed that the *CCR5Δ32* allele is almost in complete linkage disequilibrium with *CCR2-64I*: the two mutations are not found together on the same chromosome. In European populations about 20 percent of the population will carry one of the two mutant alleles (Romano-Spica et al. 2000). However, unlike *CCR5Δ32*, *CCR2-64I* does occur in African populations (Su et al. 1999), where there are slow progressors, despite the much shorter median time from seroconversion to acquired immunodeficiency syndrome (AIDS).

A point mutation in the 3′UTR of the gene coding for SDF-1α, the ligand for CXCR4, *SDF1-3′A* has a recessive protective effect, unlike the effect of *CCR2–64I* which is dominant. Homozygotes make up about 1 percent of Caucasian populations and these people show a much slower disease progression. The frequency of *SDF1-3′A* varies worldwide with high frequencies in Oceanian populations (Su et al. 1999). An *SDF1* heterozygous genotype is one factor implicated in infectivity and hence in mother-to-offspring transmission (John et al. 2000).

Genetic variation has also been studied with respect to other chemokine ligands including MIP-1α, RANTES, and eotaxin (Liu et al. 1999; Modi et al. 2000; Gonzalez et al. 2001). Two polymorphisms in the *SCYA5* promoter at positions −403 and −28 result in GC, AC, and AG haplotypes. The −28G allele, which occurs at a frequency of 17 percent in noninfected Japanese, was associated with reduced $CD4^+$ lymphocyte depletion rates in HIV-1-infected individuals and increased transcription of the RANTES gene (Liu et al. 1999). Homozygosity for the *SCYA5* AC haplotype was associated with increased risk of acquiring HIV-1 as well as accelerated progression in Europeans, but not African–Americans, despite a high prevalence of the haplotype in people of African origin (Gonzalez et al. 2001).

In contrast to the work on chemokines, there has been little consideration of the effects of cytokine polymorphism on HIV-1 infection (Nakayama et al. 2002; Shin et al. 2000). In general findings are weak and concern disease progression. Similarly, there are few studies on the role of genes involved in innate immunity and immunomodulation such as *NRAMP1* (Marquet et al. 1999), *MBL* (Pastinen et al. 1998), and *VDR* (Hill 1998). In a Colombian population four *NRAMP1* genotypes were associated with altered risk of infection. Three genotypes were associated with reduced relative risks (0.24–0.35), but were in strong linkage disequilibrium, and one genotype was associated with an increased relative risk (2.29) (Marquet et al. 1999). Heterozygotes for a *VDR* polymorphism are at reduced risk of infection (Hill 1998).

In contrast there are many observations concerning HIV-1 susceptibility and progression according to HLA type. Findings are variable, which may be in part accounted for by diverse ethnic background (Al Jabri 2002). *HLA-B*35-Cw*04* is associated with rapid progression in white Europeans and, although cytotoxic T lymphocytes (CTL) have been observed to recognize epitopes in the context of *HLA-B*3501*, analysis of subtypes suggests that a single amino acid change may be key (Gao et al. 2001). Lack of alleles *HLA-B*35* and *HLA-Cw*04*, together with full heterozygosity at HLA class I loci, has been associated with extended survival (Carrington et al. 1999). It is interesting in this context that lack of diversity at chimpanzee class I loci has been highlighted in relation to their natural resistance to AIDS: it has been proposed that a selective sweep has occurred as a result of exposure to simian immunodeficiency virus (SIV) or a closely related retrovirus (de Groot et al. 2002). Another well-characterized haplotype, *HLA-A1-B8-DR3*, is associated with rapid progression, and some autoimmune conditions (Candore et al. 1998; Price et al. 1999). Such associations with extended haplotypes raise the possibility of the involvement of class III loci such as *TNF* (Khoo et al. 1997).

Finally, there are some studies concerning the susceptibility to opportunistic infections associated with HIV-1, e.g. inflammatory cytokine and Fc receptor genes have been examined for influence on susceptibility to Kaposi's sarcoma, itself associated with human herpesvirus 8, with some significant associations (Foster et al. 2000; Lehrnbecher et al. 2000).

HTLV-1 and HTLV-2

Human T-cell lymphotropic virus (HTLV)-1 and HTLV-2 are retroviruses where, from rodent models, it may be expected that host genetic background will influence clinical manifestations. HTLV-I causes adult T-cell leukemia/lymphoma (ATL), HTLV-1-associated myelopathy/tropical spastic paraparesis (HAM/TSP), and HTLV-1 uveitis (HU) in a small percentage of infected carriers. Most human genetic studies have been on the MHC. HLA haplotypes have been examined for ATL patients, and a TNF_{-857} allele, associated with enhanced production of TNF-α, correlated with enhanced susceptibility to ATL in Japanese (Tsukasaki et al. 2001). Class II alleles differ among patients developing ATL or HAM/TSP (Manns et al. 1998). An HLA effect for HAM/TSP would be consistent with the suggestion that pathology for this condition is the result of an exaggerated CTL response (Bangham et al. 1999). Concurrence of HAM/TSP and HU is relatively common, but concurrence of either with ATL is rare. *TNF* promoter alleles at positions −1031 and −863 have been proposed as risk factors for HU (Seki et al. 1999). Although many of these studies have considered linkage disequilibrium, elucidation of genetic effects is still in the early stages.

Respiratory syncytial virus

Respiratory syncytial virus infection results in bronchiolitis in a proportion of infected children. Pathology is correlated with neutrophils and IL-8 production. An *IL8* promoter allele was associated with increased IL-8 production in LPS-stimulated blood, and was more frequently transmitted by parents to offspring with bronchiolitis (Hull et al. 2000). This observation has been confirmed and a detailed haplotypic analysis of the region conducted using six SNPs. The putative disease allele resided on two haplotypes, only one of which was implicated in disease, suggesting that the original polymorphism was not functional (Hull et al. 2001). Consistent with observations from other loci, Europeans have few common haplotypes differing at multiple sites whereas Africans show greater haplotypic diversity. There is also some evidence for a role of *IL4* (Choi et al. 2002), and possibly *IL4RA*, in severe bronchiolitis (Hoebee et al. 2003).

In addition to the retroviruses described above, a group of viruses showing latent or asymptomatic infections, with later pathological consequences in a subset of individuals, have been considered for human immunogenetic determinants. These include hepatitis B and hepatitis C, Epstein–Barr virus (EBV), papilloma viruses, cytomegalovirus (CMV), and herpesviruses.

Hepatitis B and hepatitis C

In mice, two non-*H-2*-linked genes have been proposed to determine susceptibility to hepatitis viruses (*Hv1* and *Hv2*; McLeod et al. 1995). Host genetics may be involved in several aspects of infection. Infection may be transmitted from an infected mother to a child perinatally, and there are racial differences in the frequency of perinatal transmission, implicating genetic control. Twin studies in China employed several different markers of hepatitis B (HBV) infection (Lin et al. 1989). No significant difference in the concordance of HBV infection was observed in the monozygotic and dizygotic twins; however, significant differences were seen between twins and controls. Highly significant differences were seen in the concordance of carrier status between monozygotic and dizygotic twins, indicating that genetics may be involved in the persistence of hepatitis B. MHC genotype is a risk factor for developing persistent infection. In addition, the MHC may be involved in nonresponsiveness to immunization. Both carriage of certain MHC alleles and MHC heterozygosity may be important in protection from persistent infection. In a west African population, where 90 percent of adults have been infected and 15 percent have persistent infection, there was some heterozygote advantage for the class II but not for the class I region, as well as a protective association with *HLA-DRB1*1302* (Thursz et al. 1997; Hill 1998). Two further studies have shown this allele or its supertype *HLA-DR6* to be protective. However, in a small Qatari study *HLA-DR2* was associated with clearance and *HLA-DR7* with persistence (Almarri and Batchelor 1994). Heterozygote advantage was confirmed in a study of largely African–American intravenous drug users, which found persistence associated with *HLA-DQA1*0501, DQB1*0301*, and class II homozygosity (Thio et al. 1999). The different allelic associations seen in this study were ascribed to the different age of initial infection. In addition to class II, *TNF* promoter and *VDR* alleles have been associated with HBV clearance (Hill 1998; Bellamy et al. 1999), and in Africans, but not other populations, *MBL* does not appear to influence the risk of HBV persistence (Bellamy et al. 1998b).

A particularly interesting set of questions relates to the chronic persistence of HBV as a risk factor for hepatocellular carcinoma (Wild and Hall 1999). It is possible that even apparently immune individuals are responding to sequestered virus, and risk factors for hepatocellular carcinoma include not only persistent infections such as HBV, but also other lifestyle, environmental, and genetic aspects. It seems likely that HLA determines development of hepatocellular carcinoma in hepatitis B antigen-positive patients (Donaldson et al. 2001). Susceptibility is also reported to be associated with genetic variation in the enzymatic detoxification of aflatoxin B1 (McGlynn et al. 1995), and variation in the gene for cytochrome P450 1A1 (*CYP1A1*), involved in transforming tobacco polycyclic aromatic hydrocarbons into carcinogenic metabolites, affects the risk of hepatocellular carcinoma in smokers (Yu et al. 1999). The complex mechanisms and interactions of these many factors remain to be elucidated.

The more recently described hepatitis C (HCV), like hepatitis B, is successfully cleared only in a minority of individuals. In the persistently infected, some remain asymptomatic whereas others progress to hepatocellular carcinoma. Again the role of HLA has been examined at a number of stages: susceptibility itself, viral clearance, progression to hepatocellular carcinoma, and response to treatment (Donaldson 1999). The first of these questions is dogged by the bugbear of all infectious disease immunogenetics, exposure. The second is the best studied, e.g. in the UK Minton et al. (1998) reported *HLA-DRB1*1101* (a *DR5* allele) and *HLA-DQB1*0301* to be associated with clearance of hepatitis C. This supports a previously observed protective effect of *HLA-DR5* (Zavaglia et al. 1996), although haplotypic analysis suggests *HLA-DQB1*0301* as being key (Alric et al. 1997; Donaldson 1999). However, a number of studies do not fit with such associations (e.g. Lechmann et al. 1999), although some of these studies have relatively small sample sizes. A suggestion that some of the disparities were the result of ethnic diversity (Thio et al. 2001) has stimulated some discussion (Sarmiento et al. 2002). Kuzushita et al. (1998) examined the effects of

HLA on progression to liver damage in HCV-infected subjects and showed that haplotypes that included *HLA-B*54* were associated with liver damage, whereas haplotypes that included *HLA-DRB1*1302-DQB1*0604* were associated with low hepatitis activity. The less frequent alleles of the TNF_{-308} and TNF_{-238} polymorphisms were correlated with development of cirrhosis in hepatitis C carriers (Yee et al. 2000); however, *TNF* has not been studied in conjunction with class I and II alleles. Sustained response to antiviral therapy has been associated with *IL10* but not *TNF* haplotypes (Yee et al. 2001). Outcomes of hepatitis C infection have also been correlated with variation in the gene for the low-density lipoprotein receptor (*LDLR*), apparently through effects on immune function rather than receptor status (Hennig et al. 2002).

Patients with liver–kidney microsomal type 1 antibodies often have detectable hepatitis C. In the presence of hepatitis C, a correlation was seen between the presence of antibodies and *HLA-DR7* in a Spanish study (Jurado et al. 1997), whereas *HLA-DR3* correlated with serum cryoglobulinemia and *HLA-DR4* with serum autoantibodies in a Chinese population (Hwang et al. 2002). The etiologically distinct autoimmune hepatitis, which is not caused or triggered by viral infection, also has well-characterized HLA associations. In addition non-HLA genes may be involved: in studies of *IL1*, *IL10*, *TNF*, and *CTLA4*, susceptibility to type 1 autoimmune hepatitis was associated with *CTLA4* alleles and TNF_{-308}*2 which is interdependent with *HLA-DRB1*0301* (Cookson et al. 1999; Djilali-Saiah et al. 2001).

Other viral infections

A number of other viruses are also associated with specific malignancies. As for hepatitis, there is often evidence for both genetic susceptibility to the virus itself, and genetic susceptibility to malignancy after infection. However, these questions are sometimes difficult to unravel.

Epstein–Barr virus is associated with a variety of malignancies. Interestingly, from a geneticist's point of view, racial groups show clear differences in the type of malignancy, with Burkitt's lymphoma in African populations and nasopharyngeal carcinoma in east Asian populations. It has been proposed that pathogenesis is a result of a failure of EBV-specific immunity (Niedobitek et al. 2001). EBV is ubiquitous and there has been some consideration as to the mechanism by which HLA could control primary infection, either as a co-receptor for viral entry (Haan and Longnecker 2000) or by influencing T-cell precursor frequencies (Toussirot et al. 1999). *IL10* promoter polymorphisms appear to influence susceptibility to primary infection (Helminen et al. 1999, 2001). HLA class I and II, *TNF*, and *IL10* may all play a role in susceptibility to EBV-associated gastric carcinoma (Koriyama et al. 2001; Wu et al. 2002b). *HLA-A*0207*, which is common in Chinese but not Caucasian populations, is associated with nasopharyngeal carcinoma (Hildesheim et al. 2002). *HLA-A*0207* is in linkage disequilibrium with *HLA-B*4601*, a previously identified risk factor, and *HLA-A*1101* is protective. A recent genome scan of Chinese families with nasopharyngeal carcinoma, and using parametric linkage analysis, identified a single region on chromosome 4, with a LOD score of 3.67 to marker D4S405, which was increased by incorporation of information on EBV antibody titer (Feng et al. 2002).

The human papilloma viruses (HPV) infect the squamous epithelial cells of skin, the oral cavity, and the cervix, leading to warts and in some cases cancer. The viral E6 oncoprotein binds to the tumor suppressor p53 and induces degradation. The degradation is affected by a Pro/Arg variation at position 72 in p53, with homozygosity for the Arg variant resulting in increased susceptibility to HPV-16/-18 infection and oral carcinogenesis (Nagpal et al. 2002). Similarly, there is genetic predisposition to cervical cancer (Magnusson and Gyllensten 2000), with MHC involvement, although findings are mixed. *HLA-B53* was found to be at increased frequency in patients with cervical neoplasia and HPV of types other than 16 or 18, whereas *HLA-B55* was increased in HPV-negative neoplasia patients (Krul et al. 1999). MHC II associations have also been reported. In the context of immunization, some HPV-16 E7 oncoprotein epitopes bind to the products of several *HLA-A2* alleles (Ressing et al. 1999).

HLA associations for infection with other human viruses have been identified. HLA restriction of the immune response to dengue virus may affect vaccine development (Loke et al. 2001), and known variation in response to immunization, correlated with HLA restriction, such as in the case of measles, may influence worldwide population vaccine efficacy (Poland 1999). Other genes may influence viral outcome, such as *VDR* and *FCRG2A* in susceptibility to severe dengue hemorrhagic fever (Loke et al. 2002).

In a number of instances, murine studies are well ahead, as with the murine leukemia virus-mapped genes (Malo and Skamene 1994; McLeod et al. 1995). There are at least two regions controlling CMV in mice: the MHC and *Cmv1*. *Cmv1*, an autosomal dominant gene, controls virus replication in the spleen and mediates its effects through NK cells. MHC associations in human CMV infection are also seen and could be caused partly by an effect of the proinflammatory *TNF* gene (Hurme and Helminen 1998). Influenza is controlled by *Mx1* in mice and has been cloned (Malo and Skamene 1994). In susceptible laboratory strains there is a deletion of exons 9–11, or alternatively a point mutation in exon 10, resulting in a stop codon. *Mx1* is controlled by interferons α and β, and has been highly conserved in

evolution, being present in all eukaryotes. A gene *Mx2* has also been identified that controls vesicular stomatitis virus in mice. The human homologs will be of interest. Of topical interest is host genetic susceptibility to West Nile Virus, a flavivirus, where a mutation in the gene coding for IFN-γ-inducible 2′,5′-oligoadenylate synthetase is associated with murine susceptibility (Samuel 2002).

Prions

The *PRNP* gene encodes the prion protein (PrP). Classification of prion diseases has been as genetic, infectious, or sporadic; however, all involve modification of PrP (Pruisner and Scott 1997). Approximately 10 percent of prion disease is inherited. There are several mutations in *PRNP* available for study (Kovacs et al. 2002), e.g. the murine equivalent of the PrP P102L mutation, associated with Gerstmann–Straussler syndrome, alters incubation time of transmissible spongiform encephalopathy (Manson et al. 1999). Most notably, all patients to date with variant Creutzfeldt–Jakob disease, and many with sporadic Creutzfeldt–Jakob disease, are homozygous *PRNP* for a methionine at position 129, whereas heterozygotes are protected (Palmer et al. 1991; Windl et al. 1996; Zeidler et al. 1997). The kuru epidemic in New Guinea also preferentially affected individuals with the *PRNP129* M/M genotype, resulting in complete loss of this genotype from affected communities (Lee et al. 2001). Undoubtedly *PRNP* does not act as a sole determinant of disease. Studies in other species, including mice, have searched for additional genetic components. A PrP-like protein, doppel protein, is coded for by *PRND*, close to *PRNP*. Whether variants of *PRND* will influence human prion disease directly, or merely reflect variation in *PRNP*, remains to be established (Peoc'h et al. 2000; Schroder et al. 2001). A recent study implicated HLA in variant Creutzfeldt–Jakob disease, with patients showing a reduced frequency of *HLA-DQB1*0301/4/9* (Jackson et al. 2001). This was an exciting finding, because it was thought to explain why many putatively infected, *PRNP*-susceptible, individuals did not develop disease. However, this finding has not been supported (Laplanche et al. 2003; Partanen 2003; Pepys et al. 2003).

BACTERIAL INFECTIONS

Intracellular bacteria

A number of intracellular bacteria have been investigated for control of infection by host genetic factors. In particular, there have been many studies of bacterial pathogens of macrophages, and these studies may be considered together with those concerning protozoal macrophage parasites such as *Leishmania* spp. Mycobacterial species have been a focus of attention and *Mycobacterium tuberculosis* and *Mycobacterium leprae* are considered separately.

Whereas common genetic variation has been proposed to influence the major infectious diseases, the mycobacteria also provide good examples of rare host deleterious mutations resulting in disease caused by poorly pathogenic bacteria (Ottenhoff et al. 2002). The main infections observed are disseminated *Mycobacterium bovis* BCG and *Mycobacterium avium*, although infections with *Salmonella* spp. also occur (Jouanguy et al. 1999a). The underlying phenotype is of defective bacterial killing resulting from a failure to produce or respond to IFN-γ, and fatal infection is common. Deficiencies may be partial or complete, and inherited in either a recessive or a dominant fashion. These deficiencies are often caused by mutations in cytokine receptor genes, and a variety of mutation types occur (Ottenhoff et al. 2002). The first mutations were identified in Maltese and Tunisian patients (Jouanguy et al. 1996; Newport et al. 1996), where genome scanning for regions of homozygosity in Maltese individuals pinpointed a premature stop codon in *IFNGR1* (Newport et al. 1996). Functional studies confirmed the genetic observations (Newport et al. 1996; Altare et al. 1998b). Later studies identified a deletion hotspot in *IFNGR1* downstream from the mutations first identified (Jouanguy et al. 1999b). These studies were rapidly followed by the identification in other patients of IL-12R deficiency, as a result of premature stop codons in the gene for the β1 subunit of the IL-12R (*IL12RB1*) (Altare et al. 1998a; de Jong et al. 1998). A recent report of complete IL-12Rβ1 deficiency in 41 patients from 17 countries reported a fair prognosis and discussed the redundancy of IL-12 in immunity (Fieschi et al. 2003). To date, mutations have been identified in three further genes, encoding IL-12 p40 (*IL12B*), IFN-γR2 (*IFNGR2*), and STAT1. The p40 subunit of IL-12 principally interacts with the β1 subunit of the IL-12R. Other cytokines and receptors may also have a phenotypic role, such as IL-23, which shares the p40 subunit with IL-12, and IL-23R, which shares IL-12Rβ1 with IL-12R (Ottenhoff et al. 2002). Overlapping cytokine and receptor specificities may account for the appearance of mutations in only a proportion of subunits.

Phenotypic severity in such patients correlates with the degree of impairment of IFN-γ pathways. Complete deficiency of IFN-γR1 and IFN-γR2 are the most severe (Ottenhoff et al. 1998). However, disease phenotype heterogeneity is consistent with involvement of other genetic or environmental factors, in addition to primary mutations (Picard et al. 2002). Indeed such rare deficiencies may be regarded as being at one end of a continuous spectrum of disease severity, with common variation contributing to responses to more pathogenic organisms at the other end of the spectrum. Unlike

variation in proinflammatory cytokine genes, and type 2 cytokine and receptor genes, there is little evidence that common variation in type 1 cytokine pathways plays a significant role in noninfectious disease susceptibility.

Studies of common variation in other candidate genes for the less common mycobacterial pathogens, such as *NRAMP1* in *Mycobacterium avium-intracellulare* infections, sometimes associated with HIV, and *Mycobacterium ulcerans* infections, not known to be HIV associated, have not shown allelic associations (Huang et al. 1998; Stienstra et al. 2001).

Leprosy

The clearly defined spectrum of clinical disease in leprosy, from lepromatous to tuberculoid forms, and the slow progression of disease, has long attracted the interest of geneticists. There is also evidence that the incidence of leprosy infection is much higher than the incidence of clinical leprosy, with 95 percent of those infected proposed to have persistent or self-curing subclinical infection (Fine 1983). A genetic predisposition to leprosy has been speculated upon for more than 50 years (Fine 1981; Schurr et al. 1991), with observations of racial differences and familial clustering, although it has been difficult to differentiate between genetic effects and shared environment. Further support for the role of genetics was obtained using twin studies, where concordance in monozygotic twins is consistently higher than in dizygotic twins (Schurr et al. 1991). Studies implicate genetic predisposition to position on the leprosy spectrum as well as to the disease itself. More formal proof has been obtained from family studies, using a variety of methods including complex segregation analyses, carried out on a number of American and Asian populations (Haile et al. 1985; Shields et al. 1987; Abel and Demenais 1988; Wagener et al. 1988; Abel et al. 1992b; Feitosa et al. 1995; Shaw et al. 2001). All studies have demonstrated the importance of host genetics, but, whereas some results suggest major gene control of susceptibility to leprosy itself, there has been no consensus as to the precise mode of inheritance, or to genetic control of severity. Such mixed results may be accounted for in part by limitations of the methods employed, partly by population heterogeneity and partly by strong environmental confounding factors (Feitosa et al. 1995), e.g. segregation analyses rely on liability classes, which should be derived from accurate epidemiological information. Early papers tested only single gene and multifactorial models, whereas a later study used the program COMDS which allowed testing of an oligogenic model (major gene plus additional genetic effects, Shaw et al. 2001). In this study, data from 76 Brazilian multicase leprosy pedigrees supported a two-locus model as the best fit: a recessive major gene plus a recessive modifier gene.

There has been a single recent human genome scan for susceptibility to leprosy (Siddiqui et al. 2001). This study was carried out using 245 affected sib-pairs from an Indian population where leprosy was predominantly tuberculoid. Significant linkage was obtained for a single chromosomal region, 10p13. Surprisingly, there was no linkage to HLA. Further evaluation with 140 additional families, for a region that had shown weak evidence of linkage in the genome scan, identified linkage to a second region at 20p12 in families from Tamil Nadu, but not Andhra Pradesh (Tosh et al. 2002). Transmission disequilibrium testing was employed for fine mapping of the chromosome 20 region, and showed that a marker, D20S835, was associated with protection against leprosy, and presumably lies close to the susceptibility locus. Neither 10p13 nor 20p12 contains obvious candidate genes. These results remain to be investigated in other populations.

The earliest linkage studies of HLA and leprosy involved the observation of nonrandom segregation of parental HLA haplotypes (de Vries et al. 1976; Fine et al. 1979), whereas later studies have also employed parametric linkage approaches (Haile et al. 1985; Dessoukey and El-Shiemy 1996; Shaw et al. 2001), in some instances using information on mode of inheritance derived from the same population. Linkage to the HLA region has been observed in Surinamese, Indian, Egyptian, and Brazilian families. Maximum LOD scores are found at a recombination fraction of 0, directly implicating the MHC (Shaw et al. 2001). Evidence for HLA control has often been found using tuberculoid siblings, but, as this is often the most common type of leprosy, further conclusions on the role of HLA are difficult. A 1976 study reported an increase in haplotype sharing between siblings with similar leprosy type, whereas siblings with different types of leprosy shared haplotypes less often than expected (de Vries et al. 1976). This led to the suggestion that two HLA genes were involved, determining susceptibility to leprosy itself and severity of leprosy, respectively, an idea that remains to be confirmed or refuted.

Some of the many HLA association studies have been reviewed (Todd et al. 1990; Meyer et al. 1998). Results have been variable, and such inconsistencies may reflect the lack of power of studies, variable selection of controls, and statistical false positives, in addition to population heterogeneity. HLA class I associations have not been highly reproducible, and perhaps the only study of note is an *HLA-A11* association which has been reported with erythema nodosum leprosum, seen in some multibacillary patients (Agrewala et al. 1989). The clearest associations, found in several ethnic groups, are for MHC class II: *HLA-DR2* is often associated with both lepromatous and tuberculoid leprosy, and *HLA-DR3* is associated with tuberculoid leprosy. *HLA-DQw1* may also be a susceptibility allele (Jawinska and Serjeantson 1988; Todd et al. 1990). Further resolution

of susceptibility and resistance class II haplotypes has been achieved in later studies, and some HLA influence, at least on disease severity, seems certain.

A number of studies have also been performed on HLA control of in vitro immune responsiveness, usually using crude mycobacterial antigens. However, HLA-restricted mycobacterial epitopes might be expected to elicit protective or suppressive immune responses. Although little is known about the nature of such epitopes (Meyer et al. 1998), potential leprogenic motifs are suggested from the observation that arginine residues in the peptide-binding groove of *HLA-DRB1* at codons 13 or 70–71 in pocket 4 conferred a relative risk for tuberculoid leprosy of 8.8 in Indian leprosy patients compared with healthy controls (Zerva et al. 1996). Eleven *HLA-DRB1* motifs positively associated with leprosy in a Nigerian population tended to have basic residues at codons 13, 70, 71, 74, and 86, resulting in a net positive charge, whereas five negatively associated motifs were characterized by acidic residues and a net negative charge (Uko et al. 1999).

It is still possible that observed associations are merely a reflection of linkage disequilibrium occurring within the HLA region, such as with the *TAP2* locus within the class II region showing allelic association with tuberculoid leprosy (Rajalingam et al. 1997). However, studies on *TNF* in the class III region suggest that there may be multiple susceptibility genes in the HLA region. In a study of Indian leprosy patients TNF_{-308}*2 was found at increased frequency in lepromatous but not tuberculoid patients (Roy et al. 1997), an allele commonly thought to be associated with high TNF-α production. In contrast, use of the transmission disequilibrium test for Brazilian leprosy families revealed an association of TNF_{-308}*1 for all types of leprosy (Shaw et al. 2001). Two-locus transmission disequilibrium testing for the class III region identified *TNF*1/LTA*2* as a susceptibility haplotype, *TNF*2/LTA*2* as a resistance haplotype, and *TNF*1/LTA*1* as not associated with leprosy. This confirms that the TNF_{-308} polymorphism is not the whole story. The complex influence of such haplotypes is in accordance with studies on other infectious diseases and this region. *TNF* is also an excellent candidate gene for nerve damage and leprosy reactions, commonly associated with high levels of circulating TNF-α, although no convincing associations have been shown to date (Sarno et al. 2000). There have been no association studies for the other proinflammatory cytokine IL-1. A recent study of Toll-like receptor 2 suggests a promising avenue for exploration (Kang and Chae 2001).

NRAMP1 might be expected to play a role in human susceptibility to leprosy, because susceptibility to *M. lepraemurium* is determined by a single amino acid change in *Nramp1* in inbred mouse strains. Analysis of *NRAMP1* haplotype sharing in predominantly Vietnamese leprosy families, containing both lepromatous and tuberculoid patients, showed significantly nonrandom sharing (Abel et al. 1998), conflicting with two earlier small studies that failed to find evidence of linkage (Shaw et al. 1993; Levee et al. 1994). However, parametric LOD score analysis, on an extended haplotype, showed only very weak evidence for linkage, and no specific allelic associations were identified. A Malian association study found that, for one *NRAMP1* polymorphism, in the 3′UTR, heterozygotes were more common in lepromatous than tuberculoid patients (Meisner et al. 2001). This finding was not reproduced in Indian patients (Roy et al. 1999). No associations were found for leprosy as such. From limited information, it does not appear that *NRAMP1* is a major player in human susceptibility to *M. leprae*. An investigation of skin test responsiveness to lepromin, using the predominantly Vietnamese families, showed linkage of positive Mitsuda reaction to *NRAMP1* (Alcais et al. 2000), building on the observation of familial aggregation of positive Mitsuda reaction in Brazilians (Feitosa et al. 1996). Although linkage was independent of leprosy status, the suggestion that a Mitsuda reaction can be used as a predictor of susceptibility to lepromatous disease makes precise interpretation of these findings difficult.

The *VDR* codon 352 polymorphism has also been examined in Indian leprosy patients (Roy et al. 1999). The homozygous genotype previously associated with low bone mineral density, enhanced clearance of hepatitis B and resistance to pulmonary tuberculosis (TB) was more common in tuberculoid patients than in controls. In contrast, homozygosity for the opposing allele was more common in lepromatous patients than in controls.

Tuberculosis

Studies of genetic susceptibility to *M. tuberculosis* are somewhat fewer than those for *M. leprae*. This may be the result of a less marked contribution of HLA, problems of ensuring reliable diagnosis, and a less polarized spectrum of disease. Almost all genetic studies concern pulmonary TB, and other disease manifestations have been sadly neglected. Twin studies do suggest genetic control of pulmonary TB, with concordance in monozygotic twins being substantially higher than in dizygotic twins (Comstock 1978; Fine 1981; Bellamy and Hill 1998). However, estimates of heritability vary widely. There is a single formal study of genetic control of susceptibility to TB, where complex segregation analysis pointed to oligogenic control of TB in a Brazilian population (Shaw et al. 1997). The lack of more formal proof is surprising in view of efforts expended in gene identification.

The majority of gene studies have employed a candidate gene approach, with HLA, including *TNF*, the *IL1*

gene cluster, *NRAMP1*, *MBL*, and *VDR*, all receiving attention. In particular, investigation of *NRAMP1* was triggered by the observations of single gene control of mycobacterial species made in mice more than 20 years ago. Recently, a genome scan in mice has suggested further regions (Lavebratt et al. 1999). However, although murine genome scan results on mycobacterial and leishmanial species are correlated, there is no obvious correlation with patterns seen in humans. A human genome scan using Gambian and South African sib-pairs, and a derivation of homozygosity mapping, dependent on common ancestry, showed suggestive evidence for linkage of TB to chromosomes 15q and Xq (Bellamy et al. 2000). Fine mapping of the 15q11–13 region implicated a gene *UBE3A* coding for ubiquitin protein ligase E3A, or a close flanking gene (Cervino et al. 2002). It remains to be seen whether regions identified from genome scans prove to be more important than previously studied candidate genes, or whether such regions turn out to be study-specific.

As for many infectious diseases HLA has been a candidate region for control of susceptibility. In the case of TB this has been supported by murine studies. However, fewer human studies have been conducted than for leprosy. Most studies have been carried out in association with pulmonary TB and, although results are not consistent between small population groups and there are potential problems of population stratification, a number of studies have reported an association with *HLA-DR2* (later *HLA-DRB1*1501*, reviewed in Meyer et al. 1998). Studies in Indian populations have genotyped additional loci within the class II region (*HLA-DQA1*, *-DQB1*, and *-DPB1*), in an effort to determine susceptibility haplotypes (Mehra et al. 1995; Ravikumar et al. 1999). Consideration of *TAP* genes, also within the class II region, points to a complex picture of haplotypes contributing to disease susceptibility (Rajalingam et al. 1997). TB is a common opportunistic infection in immunosuppressed patients and it is likely that HLA associations in nonimmunosuppressed and immunosuppressed cases will differ. Whereas *HLA-DQA1*0101*, *HLA-DQB1*0501*, and *HLA-DRB1*1501* were risk factors for TB in nonimmunosuppressed Mexican patients, *HLA-DRB1*1101* appeared to influence disease in HIV-infected patients (Teran-Escandon et al. 1999). Unlike several other infectious diseases, including leprosy, limited attempts to find linkage or association to *TNF* in the class III region have often proved negative (Shaw et al. 1997; Goldfeld et al. 1998; Selvaraj et al. 2001). As linkage disequilibrium between class II and III regions is rarely considered, and rarely formally tested, the relative contributions of distinct loci are sometimes hard to unravel. At a minimum, *TNF* is not a major contributor to disease susceptibility.

A few studies have tested the effect of HLA on immune response phenotypes. Most, but not all, concern cellular responsiveness (Bothamley et al. 1989; Jepson et al. 1997b). Selection of active, cured, or relapsed patients may account for some of the discrepancies in the literature. In a small study of Mexican–Americans, where *HLA-DR3* was at a reduced frequency in TB patients, there was an indication of an HLA effect in patients for in vitro proliferation to purified protein derivative (PPD) (*HLA-A9-B40* in strong responders and *HLA-B14-DR1* in weak responders), but not skin test responsiveness (Cox et al. 1988). These findings contrasted with several earlier studies. In a much later study, patients carrying *HLA-DR2* showed an increased proliferative response to *M. tuberculosis* culture filtrate antigens to patients who were *HLA-DR2* negative, whereas low responsiveness to antigen and mitogens was seen in *HLA-DR3*-positive compared with negative healthy individuals (Uma et al. 1999). However, a twin study in The Gambia suggested that non-HLA genes were more important than HLA in determining immune responses to PPD (Jepson et al. 1997b).

Studies in Gambian TB patients showed weak association with the *IL1* gene cluster, *IL1RN*2* of the 86-bp repeat in intron 2 being less common in Gambian TB patients than in controls (Bellamy et al. 1998a). A study on Gujarati TB patients in the UK also implicated the *IL1* gene cluster; however, evidence remains weak (Wilkinson et al. 1999). IL-1Ra and IL-1β induced by *M. tuberculosis* varied according to *IL1RN* and *IL1B* genotype. Although there was no association between genotype and disease, haplotypic associations were seen with tuberculous pleurisy and Mantoux responsiveness.

Polymorphisms in *NRAMP1* were originally identified with a view to ascertaining the role of this macrophage function gene in susceptibility to TB (Liu et al. 1995; Searle and Blackwell 1998). Linkage to the 2q35 region was weak (Shaw et al. 1997), but some association studies have been positive in African, Asian, and later Caucasian populations (Bellamy et al. 1998c; Cervino et al. 2000; Gao et al. 2000; Ryu et al. 2000; Ma et al. 2002). Polymorphic sites, the extent of linkage disequilibrium between these sites, and the degree of association with disease appear to vary between populations. As for HLA, associations may be influenced by fine differences in disease status such as HIV co-infection (Ma et al. 2002) and disease severity (Soborg et al. 2002). A 5′ repeat polymorphism has received attention as a result of its proposed functionality (Gao et al. 2000; Awomoyi et al. 2002), with allele 2 associated with TB and LPS-induced IL-10 production by macrophages (Awomoyi et al. 2002). Monocytes from TB patients also showed high IL-10 production, suggesting that the influence of *NRAMP1* on susceptibility to TB is, at least in part, mediated by IL-10. Roles for TNF-α and IL-1β, regulated by *NRAMP1*, were not shown in this instance. One of the most interesting recent papers shows linkage of TB to 2q35, but not to the MHC, in an extended Aboriginal Canadian family (Greenwood et al. 2000). This was unusual because linkage was conducted using a

parametric approach with an autosomal dominant mode of inheritance. Individuals were assigned to liability classes, including information on tuberculin skin test responsiveness, yielding a LOD score of 3.81 with a close marker, D2S424. This emphasized both the power of parametric approaches and the need to be mindful of confounding factors such as immunization status. Despite the identification of *NRAMP1* as a candidate gene through murine studies, and apparent major gene control in this family, differences in the role of *NRAMP1* in TB between mice and humans are evident. Studies of *MBL* have also been mixed with little association seen with TB in Gambians (Bellamy et al. 1998b), but stronger evidence for a role in Indians, independent of association of pulmonary TB with *HLA-DR2* (Selvaraj et al. 1999).

A *VDR* codon 352 genotype, associated with osteoporosis and high levels of circulating 1,25-dihydroxyvitamin D_3 (1,25-D_3), which has widespread effects on cellular immunity, showed a slightly reduced frequency in TB patients (Bellamy et al. 1999). This supports an old observation that vitamin D may be beneficial in treatment of TB, and in vitro observations that 1,25-D_3 enhance the ability of monocytes to restrict growth of *M. tuberculosis* (Bellamy and Hill 1998). More recently three *VDR* polymorphisms were studied in UK Gujaratis, in whom phenotypic vitamin D deficiency was associated with active TB. Although there was no clear association between *VDR* genotype and TB, combination of particular genotypes and vitamin D status is consistent with a contributory role of host genotype (Wilkinson et al. 2000).

Exposure to TB has been suggested to reduce the risk of developing asthma (von Mutius et al. 2000). It is highly likely that such effects are in part influenced by human genotype, particularly through cytokine genes. However, studies are limited on the role of genes such as those in the chromosome 5 cluster and susceptibility to TB. The largely non-MHC control for cellular and humoral responses to PPD also remains to be elucidated (Jepson et al. 1997b), although candidate genes already implicated in susceptibility to TB are implicated in control of lymphocyte responsiveness and tuberculin reactivity (Selvaraj et al. 2000). Overall, TB is a well-studied disease; however, candidate gene associations to date have been weak and inconsistent, with substantial differences between populations (reviewed by Delgado et al. 2002), leaving much scope for identification of further genetic effects.

Salmonellosis

Infection with *Salmonella* spp. is interesting for geneticists on a number of counts. As cited above, rare deleterious mutations in genes such as *IL12B* and *IL12RB1* result in failure to produce IFN-γ, hence the failure in granuloma formation and susceptibility to non-typhi *Salmonella* spp. (Jouanguy et al. 1999a; Lammas et al. 2002). The tiny number of studies in human populations doubtless reflects the difficulties of collecting good patient groups for an acute disease. In contrast, work on mice and chickens spans several decades. Murine infection with *Salmonella typhimurium* is controlled by *Ity* (*NRAMP1*) and *Lps*, involved in innate immunity and macrophage function, and *xid* which modulates humoral immune responses by preventing the production of antibodies against polysaccharides. *Xid* is homologous with the human gene *XLA*, which causes X-linked agammaglobulinemia, and results from mutations in Bruton's tyrosine kinase (Malo and Skamene 1994). A recent genome scan for clearance of *S. enteritidis* in mice identified three regions; one was likely to be *Nramp1* and two were previously unknown (Caron et al. 2002). However, no common variants of human *NRAMP1* were associated with susceptibility to typhoid fever in Vietnamese patients (Dunstan et al. 2001a). In the same Vietnamese population, HLA class II and *TNF* associations were identified (Dunstan et al. 2001b): haplotypes that were protective (*TNF_{-308}*1-DRB1*04*) or predisposed individuals to typhoid fever (*$TNF-_{-308}$*2-DRB1*0301*) were determined.

The second most common single gene disorder prevalent in western Caucasian populations is cystic fibrosis. Homozygosity for mutant alleles has had a massive impact on reproductive fitness. The gene determining cystic fibrosis, *CFTR*, the cystic fibrosis transmembrane conductance regulator, codes for a transmembrane Cl^- channel. About 1 in 23 people are heterozygous carriers for a mutant allele, about 70 percent of which are the ΔF508 mutation, resulting in loss of a single phenylalanine and no protein expression at the cell surface. It has long been supposed that there must be heterozygote advantage in order to maintain mutant alleles at such high frequency. One suggestion is that such an advantage might be an increased resistance of heterozygotes to fluid loss caused by response to toxins from enteric pathogens such as *Vibrio cholerae*. Alternatively it has been proposed that *S. typhi*, but not *S. typhimurium*, uses the *CFTR* to enter intestinal epithelial cells, with ΔF508 cells being partially refractory, potentially decreasing the susceptibility of heterozygous carriers to typhoid fever (Pier et al. 1998). At present there is insufficient evidence for firm conclusions (Guggino 1999).

Immunogenetic studies concerning a number of other human bacterial pathogens appear in the literature. Many are in the context of mouse model systems, where variation in disease outcome between inbred strains, associated with variation in genetic background, is suggestive of genetic control. Use of transgenic and knockout mice has given clues as to immunological mechanisms and potential candidate genes. In some instances mouse susceptibility loci have been mapped, but potentially difficult studies in humans have not

followed, e.g. the *Lgn1* gene on mouse chromosome 13 controls susceptibility to *Legionella pneumophila* (Beckers et al. 1997; Diez et al. 2003) and for *Rickettsia tsutsugamushi* a single murine gene has been mapped (Malo and Skamene 1994). In some instances there are HLA association studies, although these are looking for an effect of HLA on immune environment rather than specific phenotypes. *Pseudomonas aeruginosa* susceptibility genes are *Pscr1* and *Pscr2* in mice (listed in McLeod et al. 1995); however, in humans, the effect of HLA on pulmonary phenotype as the site of infection for *P. aeruginosa* in cystic fibrosis patients has been examined (Aron et al. 1999). Genetic studies in humans are found mainly for pathogens associated with particular pathologies of interest. These pathologies may be associated with more than a single pathogen. In some cases the bacteria are intracellular and consequent inflammatory responses are involved.

Meningococcal meningitis

The best-known infection associated with deficiency of the terminal complement components C6–C9 is *Neisseria meningitides*. Although such deficiencies are not necessarily polymorphic, but strictly speaking are rare variants, and studies are usually on individual families, they are still relatively common. Deficiencies of particular components may be the result of a variety of mutations and certain deficiencies are prevalent in certain communities (O'Hara et al. 1998). The genes *C6*, *C7*, and *C9* form a gene cluster on chromosome 5 (Alvarez et al. 1995), and linkage disequilibrium occurs between common variants and the deficiencies (Wurzner et al. 1992).

There have also been multiple studies on the role of FcγR genes in susceptibility to infection and severity of meningococcal meningitis. FcγR polymorphic forms are associated with different functional activities (van der Pol et al. 2001). The FcγRIIA (CD32) R/R131 allotype, which binds IgG2 poorly, was more common in children who had survived fulminant meningococcal septic shock than healthy controls (Bredius et al. 1994). In some cases allotypes have been reported to be similar in patients versus controls; however, the R/R131 allotype is at an increased frequency in the more severe forms of disease such as fulminant meningococcal disease and meningococcemia without meningitis (Domingo et al. 2002). R/R131 homozygous polymorphonuclear leukocytes (PMN) have reduced ability to internalize IgG2 opsonized meningococci (Fijen et al. 2000). Some of the studies have considered extended haplotypes in the FcγR gene cluster on chromosome 1.

Further genetic observations concern molecules involved in inflammation. Homozygosity for a deletion in the gene coding for angiotensin-converting enzyme (ACE), associated with higher tissue ACE, is correlated with increased disease severity (Harding et al. 2002). However, findings on *TNF* and *IL1* cluster genes have been variable. Although some resistance to a fatal outcome was found for $IL1B_{-511}$ heterozygotes, the same survey found no effect of variation in *TNF* (Read et al. 2000). In other studies, the frequency of *IL1RN*A2*, probably in linkage disequilibrium with the *IL1B* locus, and associated with increased IL-1Ra, was the same in cases and controls (Carrol et al. 2002), and the TNF_{-308} polymorphism influenced mortality as a result of meningococcal meningitis (Nadel et al. 1996). Studying first-degree relatives of meningococcal disease patients, families with low TNF-α and high IL-10 production were associated with increased risk of fatal outcome. Whereas TNF-α and IL-10 production were shown to be highly heritable, there was no difference in TNF_{-308} and TNF_{-238} genotype in relatives of survivors versus nonsurvivors (Westendorp et al. 1997).

Helicobacter pylori and gastric cancer

A twin study for infection with *H. pylori* demonstrated a heritability of 57 percent (Malatay et al. 1994). However, the greatest interest in *H. pylori* is a result of infection being a risk factor for gastric cancer. The extent of gastritis in response to *H. pylori* influences risk of cancer, with hypochlorhydria being a precursor. Gastric cancer and duodenal ulceration are mutually exclusive outcomes. Although *HLA-DQB1*0602* is increased and *HLA-DQB1*0301* decreased with different gastric cancer-associated phenotypes in Taiwanese (Wu et al. 2002a), and *HLA-DQA1*0102* associated with resistance in Japanese (Azuma et al. 1998), more complete study of the HLA class II region suggests that the limited associations observed to date are not strong enough to stand correction for multiple comparisons (Yoshitake et al. 1999). A study of three polymorphisms within *IL1B* and the $IL1RNV_{NTR}$ polymorphism demonstrated that haplotypes putatively associated with upregulation of IL-1β had an increased frequency in cases of hypochlorhydria induced by *H. pylori* and of gastric cancer (El-Omar et al. 2000). Most recently, a genome scan of Senegalese siblings used the quantitative trait of specific IgG for *H. pylori*. Linkage analysis followed by transmission disequilibrium testing pinpointed a single gene: *IFNGR1* (Thye et al. 2003). Three variants at positions −56, 318, and 450 were associated with high antibody concentrations, and were more common in Africans than Europeans, perhaps explaining the relatively low pathogenicity in Africans.

Spondyloarthropathies

Both genetic predisposition and a number of bacterial pathogens are implicated in spondyloarthropathies; in particular bacteria are triggers for reactive arthritis,

e.g. *Salmonella enteritidis* (see above), *Listeria monocytogenes*, *Yersinia enterocolitica*, *Chlamydia trachomatis*, and *Borrelia burgdorferi* (Lyme disease). A well-known HLA association is that of *HLA-B27* with ankylosing spondylitis. In fact the *HLA-B27* association is with a broad range of spondyloarthropathies, for both development and chronicity of disease. The mechanism of predisposition is unclear but could involve use of HLA-B27 as an antigen-presenting molecule or, alternatively, class II-mediated presentation of B27-derived peptides (Lopez de Castro 1998). Undoubtedly, other molecules involved in immune responsiveness for pathogens will prove to be involved (Pacheco-Tena et al. 2002). For some of the pathogens implicated in reactive arthritis, genetic studies are largely confined to mouse models, e.g. *L. monocytogenes* with a single gene identified, *Lsr1* (Malo and Skamene 1994). For others there are a handful of human studies. For *C. trachomatis* infection, which stimulates an inflammatory response, often resulting in tissue scarring, the less common alleles TNF_{-308}*2 and TNF_{-238}*2 are associated with scarring trachoma (Conway et al. 1997). TNF-α was detected more frequently in tear fluid in patients than in controls, in line with indications that the less common alleles determine higher levels of TNF-α. This is independent of an *HLA-A*6802* association with scarring trachoma. *IL4*, *IL10*, and *MBL* are not strongly implicated (Mozzato-Chamay et al. 2000). In humans, *C. trachomatis* is also known to be a cause of pelvic inflammatory disease and infertility, but there have been no genetic studies to date. In mice, susceptibility to chlamydial salpingitis and subsequent infertility is under genetic control, with both H-2 and non-H-2 genes involved (Tuffrey et al. 1992).

Periodontitis

Oral gingivitis and the more severe periodontitis are the result of mixed microbial infections. Colonizing nonpathogenic bacteria generate the conditions required for secondary species, which tend to be gram-negative anaerobes. The outcome depends both on the species of bacteria and on the human inflammatory response. Hence the multitude of genetic studies often concern the inflammatory responses and consequent pathology, not necessarily susceptibility to bacterial species as such. Bacteria associated with gingivitis include *Streptococcus*, *Actinomyces*, *Haemophilus*, and *Capnocytophaga* spp. whereas tissue-damaging species associated with chronic periodontitis include *Porphyromonas gingivalis*, *Prevotella intermedia*, and *Bacteroides forsythus*, and with aggressive periodontitis *Actinobacillus actinomycetemcomitans*. There are case–control studies for candidate genes. In many instances the studies are small and cross-sectional, and use few polymorphic sites. One problem of drawing together findings is the range of phenotypes and severity criteria used for analysis. Bacterial species are not usually identified. Candidate genes have included *IL2*, *IL4*, *IL10*, *TGFB1*, *TNF*, *LTA*, *ACE*, and *VDR*. Although many polymorphisms show no association, some are weakly associated, and further analysis suggests both gene–gene and gene–environment interactions (Holla et al. 2001), e.g. the gene for plasminogen activator-inhibitor I is a risk factor for periodontitis, particularly in nonsmokers (Holla et al. 2002). Perhaps the most surprising result is a consistent failure to show an effect of variation in *TNF* on susceptibility or severity, even when several polymorphisms are employed (Craandijk et al. 2002).

However, the vast majority of studies concern the *IL1* and *FCGR* gene clusters. A number of investigations have highlighted association between allele 2 of $IL1A_{+4845}$ and $IL1B_{+3954}$ and disease, which may relate to the role of IL-1 as a stimulator of bone resorption. Based on the two *IL1* associations, a predictive test has been developed. However, the usefulness of this test has been questioned (Greenstein and Hart 2002), and population differences in allele frequencies may render the test inappropriate outside western Europeans (Armitage et al. 2000). In the context of IL-1, smoking is an important risk factor, although the nature of this interaction is unclear (Lang et al. 2000; Parkhill et al. 2000; Cullinan et al. 2001; Laine et al. 2001; Meisel et al. 2002). Only a few studies have attempted to correlate *IL1* genotype with protein production in vivo or in vitro (Mark et al. 2000; Shirodaria et al. 2000). Similarly, only a few studies have sought to identify the bacterial species present (Laine et al. 2001; Cullinan et al. 2001), although *IL1* genotype may well influence bacterial flora (Socransky et al. 2000).

The genes *FCGR2A*, *FCGR3A*, and *FCGR3B* have also been widely studied. A *FCGR3B* allele has been reported to influence disease in diverse population groups: elevated in African–Americans with aggressive periodontitis (Fu et al. 2002) and, together with an *FCGR3A* allele, associated with severity of chronic periodontitis in Japanese (Kobayashi et al. 2001). *FCGR3A* is in linkage disequilibrium with *FCGR3B*. In general, allotypes with low activity have been shown to be risk factors for disease. Cells carrying the periodontitis-associated *FCGR3B* allele are less efficient at both phagocytosing and inducing an oxidative burst, in response to IgG1- and IgG3-opsonized *P. gingivalis* (Kobayashi et al. 2000). However, in a group of Caucasian patients there was no significant difference in allele frequencies between mild and severe cases of periodontitis, although the severity of bone loss was correlated with the *FCGR3A* genotype coding for a high affinity receptor (Meisel et al. 2001).

FUNGAL INFECTIONS

There have been surprisingly few studies of genetic susceptibility to fungal infections, because there are

many parallels with nonfungal infections. In several respects they provide interesting features. In many cases exposure is widespread with only a few individuals contracting clinical disease. In some instances the fungi are opportunistic infections on backgrounds as diverse as the single gene disorders, such as cystic fibrosis, to acquired immunodeficiency. Immune responses may involve macrophages (*Pneumocystis carinii* – Ezekowitz et al. 1991), *Candida albicans* – Ashman and Papadimitriou 1995), allergic immediate hypersensitivity (aspergillosis – Chauhan et al. 2000), and granuloma formation (blastomycosis, coccidioidomycosis, and histoplasmosis), granulomas themselves being a potential source of pathology. These often chronic infections are likely to be influenced by MHC genes and other genes associated with macrophage function and allergic responses (Taylor et al. 1997; Chauhan et al. 2000).

PROTOZOAL INFECTIONS

Leishmaniasis

There are a number of species of Old and New World *Leishmania*, which are transmitted by sandflies and cause visceral leishmaniasis (VL) or cutaneous leishmaniasis (CL). All are obligate intracellular macrophage pathogens. There is also intraspecific pathogen diversity, although, in a single study, *L. aethiopica* variation was not associated with clinical phenotype in humans (Schonian et al. 2000). However, the *L. infantum* zymodeme MON-1 has been associated with both VL and CL, whereas MON-24 is a common agent of CL (Belhadj et al. 2003). As for mycobacterial disease, infection can be subclinical. In some individuals with the visceral parasite *L. donovani*, post kala-azar dermal leishmaniasis (PKDL) may occur after cure of the initial disease. Similarly, in a proportion of individuals, localized cutaneous lesions are followed by severe and disfiguring mucocutaneous lesions (MCL), sometimes many years after the initial lesion. MCL is economically the most important form of CL, requiring prolonged and expensive antimonial therapy. Particular zymodemes of *L. braziliensis* may have long evolution times and high frequency of involvement in mucosal disease (Saravia et al. 1998). Other species can cause diffuse CL in rare instances. In most instances, cure is dependent on macrophage activation by IFN-γ and production of IL-4, IL-5, and IL-10 is detrimental, although roles vary according to infecting species. The proinflammatory cytokines have protective roles, with NO as a mediator of parasite killing. MCL is characterized by a hyperreactive cellular immune responses with high production of both IFN-γ and IL-4/IL-5. Rare diffuse CL patients have poor cellular immunity and produce ineffectual antibodies in a situation analogous to lepromatous leprosy. The use of *Leishmania* spp. in murine models of immune responsiveness has provided a plethora of candidate genes for study, although there is no good mouse model for MCL. However, the paucity of studies in humans is noticeable.

It is clear from murine studies that different genes may control susceptibility to different *Leishmania* spp. In some murine strains, susceptibility to the visceral parasite *L. donovani* is under single gene control, with susceptibility being recessive, caused by *Nramp1* (see earlier). *Nramp1* also affects visceralization and metastasis of the cutaneous parasite *L. mexicana* (Roberts et al. 1989), but is not involved in *L. major* infection. Findings for cutaneous parasites have been more diverse. A gene controlling chronic *L. major* lesion expansion has been mapped to a region homologous with the human 5q cluster (Roberts et al. 1993; Guler et al. 1996). As well as many candidate cytokine genes, this region is also rich in receptor genes such as that coding for the glucocorticoid receptor, which has been shown to play a role in response to *M. bovis* BCG infection in congenic mouse strains (Brown et al. 1993). Another gene, *Scl-1*, which controls healing of *L. major* lesions, has been mapped to a region of conserved synteny with human chromosome 17 (Mock et al. 1993; Roberts et al. 1993), encoding members of the cc intercrine family as inflammatory agents produced by macrophages and *NOS2A* encoding inducible NO synthase (iNOS). *Scl-2* controlling a sex-related no-lesion growth phenotype for *L. mexicana* is provisionally mapped to a region encoding IFN-α and IFN-β and Janus kinases (Roberts et al. 1990). In 1997, two murine genome scans for susceptibility to *L. major* found H-2 (chromosome 17) and a new region on mouse chromosome 9 (Roberts et al. 1997), and six regions on chromosomes 6, 7, 10, 11, 15, and 16, to be involved in susceptibility (Beebe et al. 1997). Analysis indicates some epistatic interactions between these murine loci (Roberts et al. 1999). Further studies using immunological phenotypes have identified more loci (Lipoldova et al. 2000). Many of these murine loci are unconfirmed and nomenclature is becoming a problem.

Observations on human populations have shown that the proportion of subclinical infections, the proportion of localized CL cases progressing to MCL, and the severity of MCL, vary markedly between racial groups and families (Walton and Valverde 1979). This is likely to reflect genetic variation between populations of both host and parasite. Segregation analysis and initial examination of candidate immune response genes support the role of host genetics in control of human CL. Segregation analysis of more than 2000 individuals, from a total cross-sectional survey of LCL caused by *L. peruviana* in six Andean valleys, supported a two-locus model with a major gene plus a 'modifier' locus (Shaw et al. 1995). A later study of LCL caused by *L. braziliensis* in Bolivia concluded that, in some families, a recessive major gene controlled susceptibility to the primary cutaneous lesion,

but did not consider MCL (Alcais et al. 1997). High levels of serum TNF-α are found in MCL patients, and in a small Venezuelan case–control study, a high risk of mucocutaneous disease was observed in individuals carrying *TNF$_{-308}$*2* or *LTA*2*, particularly for females (Cabrera et al. 1995). The only other studies of American CL were three studies, which found variable associations with HLA (Barbier et al. 1987; Lara et al. 1991; Petzl-Erler et al. 1991). These associations may not be primary risk factors for disease but reflect strong linkage disequilibrium.

There have been very few studies of human genetics in VL. Segregation analysis has provided support for genetic control of susceptibility, although differentiation between genetic models was poor (Peacock et al. 2001). Confounding factors, such as nutritional status, are difficult to account for in genetic studies. HLA associations with VL are weak or negative (Blackwell 1998; Meddeb-Garnaoui et al. 2001; Peacock et al. 2002). Most notably, Faghiri et al. (1995) reported a 13-fold increase in risk for VL in Iranian *HLA-A26* carriers. There is an effect of variation in *TNF* in some populations (Meddeb-Garnaoui et al. 2001; Karplus et al. 2002), with haplotypes containing *TNF$_{-308}$*2 2* associated with symptomatic VL by transmission disequilibrium testing in a Brazilian population. Despite absence of a role for *NRAMP1* in a Brazilian population (Blackwell 1998), in a Sudanese population *NRAMP1* influences susceptibility to VL/PKDL (Blackwell et al. 2003).

Toxoplasmosis

The prevalence of *Toxoplasma gondii* infection is high compared with many other pathogens, with seroprevalence varying from 20 percent to over 80 percent. The pathogenesis of disease varies: acute infection causes transient flu-like symptoms, whereas reactivation can lead to serious eye disease in immunocompetent individuals and fatal toxoplasmic encephalitis (TE) in immunosuppressed individuals. Up to 50 percent of AIDS patients who are seropositive for *Toxoplasma* spp. eventually develop TE. Progressive ocular toxoplasmosis, leading to blindness, has a sporadic distribution in most populations; however, clusters of cases occur in South America. *T. gondii* is also a major cause of congenital disease, and twin studies of human congenital infections suggest a genetic component for transplacental transmission (McLeod et al. 1995). There is relatively little variation in *T. gondii*, with a clear distinction between a subset of strains (type 1), which are regarded as acute virulent, and remaining isolates (type 2 and 3) (Howe and Sibley 1995). The majority of clinical disease in humans is caused by type 2 isolates. Limited information is available on human genetic susceptibility to phenotypes caused by *T. gondii*; however, macrophage-mediated mechanisms are of key importance in disease limitation and prevention of reactivation. There are studies of murine toxoplasmosis of phenotypes including cyst numbers in the brain and resistance to, and survival of, encephalitis. Effects of MHC class I and II genes are well established (Brown et al. 1995; Johnson et al. 2002). Other genes implicated will have substantial overlap with loci implicated in control of murine leishmaniasis, with different genes operating in acute versus chronic disease.

Trypanosomiasis

There is very little known about genetic susceptibility to African or American trypanosomes in humans. African trypanosomiasis, caused by *Trypanosoma brucei* subspecies, causes fatal sleeping sickness in humans, and is also an important cause of disease in domestic livestock such as cattle. Resistant cattle breeds are known and genome scans are being performed. Control of susceptibility to *T. congolense* in mice was largely accounted for by genes on chromosomes 1, 5, and 17 (Kemp et al. 1997). Although *H-2* on chromosome 17 is implicated, responses to challenge with trypanosomes other than *T. congolense* suggest that the MHC is not involved in murine resistance. American trypanosomiasis (Chagas' disease) is caused by *T. cruzi*, with cardiomyopathy seen in approximately 30 percent of patients. *T. cruzi* seropositivity showed a heritability of 56 percent, with an additional 23 percent of variation caused by shared household environment, in a Brazilian population (Williams-Blangero et al. 1997a). Whereas an *HLA-DRB1*14-DQB1*0301* haplotype was correlated with protection against *T. cruzi* infection in an endemic area of Peru, no HLA associations were detected for disease severity (Nieto et al. 2000). Similarly, *HLA-A30* conferred susceptibility to Chagas' disease, irrespective of the clinical presentation in Brazilian patients (Deghaide et al. 1998). As for *Leishmania* and *Toxoplasma* spp., *NRAMP1* is a good candidate gene for resistance to *T. cruzi*; however, variation in *NRAMP1* has not been shown to influence *T. cruzi* infection or cardiomyopathy to date (Calzada et al. 2001).

Malaria

There has been a large amount of work on genetic susceptibility to malaria. Aside from the long history of research on the Duffy blood group, which determines resistance to *Plasmodium vivax*, the majority of studies concern *P. falciparum* infection. Genetic factors clearly play a role in infection, development of clinical disease, and prognosis. The single gene variation associated with the red cell hemoglobinopathies is not covered in this text, nor the red cell enzyme glucose-6-phosphate dehydrogenase, or the roles of the glycophorins or band 3. This work stimulated major interest in malaria as a selective force. Malaria remains the only human

infectious disease with strong evidence for selective effects, most commonly by selection of otherwise deleterious alleles through heterozygote advantage. Perhaps because of the long history of research into genetic susceptibility and malaria, there have been few formal segregation analyses. Three west African ethnic groups living under similar conditions showed differences in a number of malarial parameters including antibody response, suggestive of genetic involvement (Modiano et al. 1996). A twin study in The Gambia suggested that risk of disease rather than infection was under genetic control (Jepson et al. 1995). Three segregation analyses are all consistent with genetic control of *P. falciparum* parasitemia in west African populations (Abel et al. 1992a; Garcia et al. 1998a; Rihet et al. 1998a) and of incidence and clinical infection in a Sri Lankan mixed *P. falciparum* and *P. vivax* area (Mackinnon et al. 2000). There are also familial correlations for some *P. falciparum*-specific cellular and antibody responses (Stirnadel et al. 1999b; Aucan et al. 2001).

It has been known for a number of years that resistance to *P. chabaudi* in mice, primarily looking at levels of parasitemia and survival, is controlled by multiple genes (Malo and Skamene 1994). More recently genome-wide approaches have identified several quantitative trait loci, named '*Char*' for chabaudi resistance (reviewed in Fortin et al. 2002). *Char1* on mouse chromosome 9 and *Char2* on chromosome 8 (Foote et al. 1997) were described at the same time as the same chromosome 8 locus and a chromosome 5 locus by a second group (Fortin et al. 1997). A third H-2-linked locus on chromosome 17 controlled parasite clearance in females (*Char3* – Burt et al. 1999). Use of recombinant congenic strains, created from strains with susceptibility alleles at *Char1* and *Char2*, identified a fourth locus on chromosome 4 (*Char4* – Fortin et al. 2001a). The genes involved have not yet been identified.

Recent human studies have concentrated on candidate genes involved in immune responsiveness and particularly severe pathology. Surprisingly, there have been few linkage studies and no genome scans.

HLA-B5301, common in sub-Saharan African populations, has been associated with resistance to severe malaria (cerebral malaria and severe malarial anemia) in Gambians (Hill et al. 1991). This observation was followed by elution of peptides from B53 and screening of candidate *P. falciparum* epitopes. HLA-B53-restricted CTLs recognized a conserved nonamer from liver stage-specific antigen 1 (LSA-1) (Hill et al. 1992). Such observations have clear implications for vaccine design and, subsequent to identification of restricted epitopes in LSA-1 for $CD8^+$ cytotoxic T cells, IFN-γ production by CTLs in response to LSA-1 peptide was correlated with protection in a Papua New Guinea (PNG) population (Bucci et al. 2000). Furthermore, the *HLA-DRB1*1302-HLA-DQB1*0501* haplotype was associated with resistance to severe malarial anemia (Hill et al. 1991). This haplotype was more common than the anticipated haplotypic association of *HLA-DRB1*1302* with *HLA-DQB1*0604* seen in Caucasian populations. In Kenyans, however, different associations were seen, with a protective effect for *HLA-DRB1*0101*, but not *HLA-B5301* or *HLA-DRB1*1302*, suggesting significant heterogeneity (Hill 1998, 1999). In a study of variants of circumsporozoite protein CTL epitopes for *HLA-B*3501*, recognition differed significantly between individuals with and those without *B*3501*, with reciprocal antagonism between variants (Gilbert et al. 1998; Hill 1998). This is one of very few studies attempting to identify directly associations between parasite and host genetics reflecting co-evolution.

However, comparison of three ethnic groups in Burkina Faso suggests that susceptibility to malaria may be correlated with immunogenetic differences other than HLA-B53 or hemoglobin S (HbS) (Modiano et al. 2001). This appears particularly true for T-cell help and antibody phenotypes (Riley 1996). Jepson found linkage of mild malaria to HLA using Gambian dizygotic twins as affected sib-pairs (Jepson et al. 1997b), and also looked at twin effects for immune responses, including those to malarial antigens and PPD. Control appeared to be largely non-MHC for cellular and humoral responses (Jepson et al. 1997a). Observation of concordance of antibodies produced in response to Pf155/RESA in monozygotic and dizygotic twins has provided evidence of genetic control, but not within the HLA class II region (Sjoberg et al. 1992). In a PNG population there were no class I or II associations for immune responsiveness to the antigens RESA and MSA-2 (Stirnadel et al. 1999a), although IgG2 against MSP2 was partly explained by class II haplotype sharing (Stirnadel et al. 2000). A strong negative association was found between antibody responses to the synthetic malaria vaccine SPf66 and *DRB1*15* (Beck et al. 1995).

The observation published in 1994 by McGuire et al. that Gambian children homozygous for TNF_{-308}*2 have a seven fold relative risk for death or severe neurological sequelae from cerebral malaria was the first of many studies of this polymorphism. This association was independent of HLA class I and II effects; however, association was with the uncommon homozygous genotype. This was followed some years later by the observation that the less common allele of another *TNF* promoter polymorphism (−238) was associated with severe malarial anemia (McGuire et al. 1999). Strangely this allele was in positive linkage disequilibrium with the protective *HLA-B53*, although in negative linkage disequilibrium with the protective *HLA-DRB1*1302*. Logistic regression analysis indicated another independent genetic effect on susceptibility to cerebral malaria caused by a polymorphism determining the transcription factor OCT-1-binding site at position −376 (Knight et al. 1999). This allele was not in linkage disequilibrium with *HLA-B53* but was in negative linkage disequilibrium

with TNF_{-308}*2, and positive linkage disequilibrium with TNF_{-238}*2, in Gambians. A contrasting Kenyan dataset showed similar findings for *TNF−376* and *TNF−308*, but a decreased susceptibility to cerebral malaria associated with TNF_{-238}*2 (Knight et al. 1999). TNF_{-376}*2 occurs only in individuals carrying TNF_{-238}*2, hence this haplotype is associated with susceptibility to cerebral malaria in Gambians, but has no effect in Kenyans. A haplotypic analysis of five *TNF* promoter SNPs in patients with cerebral malaria from Myanmar showed an effect of *TNF*-promoter diversity but not at positions −308 or −238 (Ubalee et al. 2001). Preliminary analyses of *TNF*-promoter polymorphism in other African populations have not always indicated an obvious effect (Stirnadel et al. 1999b), and in other instances only relatively mild effects on reinfection patterns (Meyer et al. 2002) and antibody responsiveness (Migot-Nabais et al. 2000). The unraveling of the complex evolutionary history of the *TNF*-promoter region has undoubtedly some way to go.

Two studies on west Africans have shown some evidence for linkage of blood parasitemia to the chromosome 5q31–q33 cluster (Garcia et al. 1998b; Rihet et al. 1998b). Although this trait remains relatively unexplored, the difficulties of getting good quantitative phenotypic information and the limited number of loci selected for testing to date leave many possibilities for further investigation. Investigation of this region in relation to anti-malarial antibody responsiveness is perhaps more tractable (Luoni et al. 2001).

NO is important in malarial pathology. In Gambians the short allele of the *NOS2A* microsatellite was associated with fatal cerebral malaria (Burgner et al. 1998). In contrast, in a longitudinal Gabonese study, the *NOS2A-954* polymorphism protected against severe malaria in the heterozygous state, and stimulated cells from heterozygous carriers showed sevenfold enhancement of iNOS activity (Kun et al. 2001). Whereas an early study suggested an inverse relationship between disease severity and NO production in Tanzanian children, these polymorphisms were not associated with disease severity, *NOS2A* expression, or NO production (Levesque et al. 1999). However, a recent study identified a new polymorphism at position −1173 (Hobbs et al. 2002). The less common allele was significantly associated with protection from symptomatic malaria in Tanzanian children and severe malarial anemia in Kenyan children. The protective allele was associated with increased fasting urine and plasma NO metabolite concentrations, in support of a protective role for NO.

There are few studies on other genes relating to IFN-γ and NO production. Consistent with a potential role of IFN-γ in susceptibility to malaria (Gourley et al. 2002), a study of *IFNGR1*-promoter polymorphisms in Gambian children showed preliminary evidence of associations with cerebral malaria in Mandinkas (Koch et al. 2002). In addition, homozygotes for an *IL12B*-promoter polymorphism showed decreased production of iNOS as reflected in urinary NO, and homozygosity was associated with fatal cerebral malaria in Tanzanian, but not severe malaria in Kenyan, children (Morohan et al. 2002).

The Duffy blood group gene (*FY*) was one of the first loci mapped on human chromosome 1, and was one of the first identified blood group systems (reviewed in Hadley and Peiper 1997). Red cells of most white Europeans are recognized by one or both anti-Fya and anti-Fyb, according to the presence of *FY*A* and *FY*B* allelic specificities. However, the null phenotype Fy(a^-b^-) is common in Africa, particularly west Africa where it is close to fixation. Fy(a^-b^-) red cells fail to be recognized by the rare anti-Fy3 which recognizes a specificity common to both Fy(a^+b^-) and Fy(a^-b^+) individuals. Fy(a^-b^-) red cells are totally refractory to invasion by *P. vivax*, making Duffy the most common immunogenetic variation resulting in an absolute effect on infectious disease susceptibility. However, the molecular basis of the Duffy system was not unraveled until the 1990s. *FY* codes for the Duffy antigen receptor for chemokines (DARC), present on the red cell surface and elsewhere, which binds to molecules such as IL-8 and RANTES. A Duffy binding ligand has been identified in the parasite. The Fy(a^-b^-) phenotype in west Africans arises from a T-to-C substitution at position −46 of an *FY*B* allele (Tournamille et al. 1995). This mutation disrupts the binding of the GATA1 erythroid transcription factor and reduces expression. More recently this same mutation has been discovered on a *FY*A* background in a PNG population, showing it to have arisen independently in at least two places, and more recently in PNG (Zimmerman et al. 1999).

ICAM-1 is thought to be involved in sequestration of parasitized red cells to the vascular endothelium. A series of observations suggests some role for ICAM-1 in malaria pathology, although, at the time of writing, the story is both complex and incomplete. A base change at position 179 results in a lysine-for-methionine substitution at amino acid 29 ($ICAM1_{Kilifi}$) (Fernandez-Reyes et al. 1997). Homozygotes had a relative risk of 2 for cerebral malaria versus nonsevere malaria in a Kenyan study, although this effect was not seen in a Gambian population (Hill 1999). The mutant allele is at a frequency of about 0.3 in Africa, which would be surprisingly high for an allele predisposing to cerebral malaria. However, comparing severe and mild malaria in a Gabonese population, $ICAM1_{Kilifi}$ appeared to be associated with protection against severe malaria (Kun et al. 1999). Functional studies have shown that $ICAM\text{-}1_{Kilifi}$ causes loss of fibrinogen binding and reduction of LFA-1 binding, suggesting a complex scenario with respect to effects of selection (Craig et al. 2000).

Another molecule thought to be involved in sequestration of parasitized red cells is CD36. *CD36* is highly polymorphic, with a number of diverse mutations resulting in CD36 deficiency. Such mutations are relatively

common in Africa. However, different mutations are present in Asian populations, and as, unexpectedly, African mutations were initially shown to be associated with susceptibility to severe malaria, it was suggested that selection pressures other than malaria were operating (Aitman et al. 2000). However, a later study of a single polymorphism in African children showed the rare allele to be associated with protection from severe malaria (Pain et al. 2001). A detailed investigation, considering common haplotypes and patterns of linkage disequilibrium, of multiple *CD36* polymorphisms in Thais concluded some protection from cerebral malaria, for mutations coding for lack of production of CD36 (Omi et al. 2003). The above investigations on *ICAM1* and *CD36*, with conflicting results, have stimulated some discussion on the importance of these molecules for malarial infection, the complexity of selection pressures operating on different populations, and whether significance levels from multiple statistical comparisons are valid (Craig et al. 2001). Although it seems likely that diversity in these two genes will prove relevant, the detail is likely to prove as complex as the story developing for the *TNF*-promoter region.

Many other genes have been investigated. Some are adhesion molecules such as *CD31* (Casals-Pascual et al. 2001; Kikuchi et al. 2001); others are receptors such as Ig receptors (Shi et al. 2001; Omi et al. 2002). However, there is no large body of work on such genes and findings are variable in different populations. There is scope for invoking malaria as a selective force in multiple populations, but it is unfortunate that other major diseases have received less consideration from evolutionary biologists.

HELMINTH INFECTION

Immune responses in helminth infection are characterized by high levels of total and specific IgE and eosinophilia, upregulated by Th2 cytokines such as IL-4, IL-5, IL-9, and IL-13. Th2 responses are protective in murine models, and there is accumulating evidence for Th2-mediated protection in human infection. Similar Th2 upregulation is seen in asthma and atopy, which are under strong genetic control. Obvious candidate genes for susceptibility to helminth infection and disease are thus those thought to be involved in the control of Th2 responses in asthma, such as the Th2 cytokine cluster on 5q, *FCER1B*, and *IL4RA*. There is evidence of genetic control of helminth infection from mouse model infections, the most commonly used being *Heligmosomoides polygyrus* and *Trichuris muris* (Wakelin and Blackwell 1988). The first genome scan for a murine parasitic nematode has just been completed for *Angiostrongylus costaricensis* (Ohno et al. 2002), with another for *H. polygyrus* in progress (Behnke et al. 2000). There is also increasing interest in sheep genes controlling gastrointestinal nematode infection.

Gastrointestinal and filarial nematodes

There is evidence for genetic control of worm burden in human populations, with heritabilities of 23–44 percent for *Ascaris lumbricoides*, *Necator americanus*, and *Trichuris trichuria* loads reported (Williams-Blangero et al. 1997b, 1999, 2002a). In contrast, studies of *A. lumbricoides* together with *T. trichuria* in Malaysians and *Strongyloides fuelleborni kellyi* in PNG did not support genetic control of worm burdens (Chan et al. 1994; Smith et al. 1991). Partitioning variance for helminth infections can be problematic, particularly partitioning genetic and household effects, and some differences may be accounted for by study design. Consideration of eosinophil rates among Brazilians infected with intestinal worms with an extra-digestive cycle, supported genetic susceptibility to helminths through influence on eosinophils (Conti et al. 1999). This finding fits well with current views on genetic control of eosinophilic inflammation (Brodie et al. 1999), and with the chromosome 5q cluster implicated in control of asthma/atopy and known to determine autosomal dominant familial eosinophilia (Rioux et al. 1998). There is less information on filarial nematode infection. A study of *Loa loa* in The Cameroons was consistent with some genetic control of microfilaremia, and a dominant major gene model was suggested (Garcia et al. 1999). Similarly genetic effects were compatible with distribution of *Brugia malayi* microfilariae, and possibly anti-filarial IgG4, in an Indonesian population (Terhell et al. 2000). However, maternal infection with *Wuchereria bancrofti* is known to be a risk factor for infection in children (Lammie et al. 1991), perhaps through early induction of immunological tolerance, which highlights potential confounding factors to genetic control. *Onchocerca volvulus*, one of the better-studied parasites for candidate genes, has not been the subject of a heritability study.

There are few small case–control studies suggesting a role for HLA in susceptibility and responsiveness to gastrointestinal nematodes (Holland et al. 1992; Satoh et al. 1999). In Venezuelan children associations were found between homozygosity for Arg16 at *ADRB2* and *A. lumbricoides* specific phenotypes, although other candidate genes on 5q33 were not investigated (Ramsay et al. 1999). This was followed by the only human genome scan for a nematode infection. Williams-Blangero et al. (2002b) genotyped 444 Nepalese, with ascaris worm burdens assessed by egg count. Quantitative trait nonparametric linkage was carried out by variance components methods and significant linkage was found to regions on chromosomes 1 and 13. The chromosome 13 region contains a candidate gene *TNFSF13B* (*BlyS*), and was also found to influence serum IgE levels. There are no obvious effects of HLA on lymphatic filariasis, either Indonesian brugian

filariasis by association (Yazdanbakhsh et al. 1995, 1997) or Polynesian bancroftian filariasis by linkage (Ottesen et al. 1981). In contrast, a small study in India suggested associations with *CHIT1* (coding for a phagocyte-specific chitotriosidase) and *MBL2* (Choi et al. 2001). It is notable that the choice of candidate genes in this study varied from those typically used for other infectious diseases. For *O. volvulus* *HLA-DQA1*0501-DQB1*0301* occurred at an increased frequency in putatively immune versus diseased individuals (Meyer et al. 1994). *HLA-DQA1*0101-DQB1*0501*, and independently *HLA-DQB1*0201*, occurred at increased frequency in individuals with generalized disease compared with localized disease and putatively immune individuals (Meyer and Kremsner 1996). In general, findings for localized disease lay between those for putatively immune and generalized disease. A follow-up study also implicated *HLA-DPA1*, with *HLA-DPA1*02011/2* having increased frequency among the putatively immune and *HLA-DPA1*0301* being associated with localized disease (Meyer et al. 1996). A methionine at position 11 of DPα1 conferred a relative risk of disease of 3.3. A later study comparing patients who had cutaneous depigmentation with patients with high microfilarial loads broadly implicated the same haplotypes (Murdoch et al. 1997). A comparison of generalized onchocercal disease versus patients with low microfilarial numbers and strong IgE responsiveness suggested some association with the Gln110Arg *IL13* polymorphism, which has also been associated with several asthma/atopy phenotypes (Hoerauf et al. 2002).

Schistosomiasis

In 1991, Abel et al. reported a segregation analysis of Brazilian families with major gene (*SM1*) control of intensity of infection by *Schistosoma mansoni*, although there has been debate over the relative role of genetics and exposure (Woolhouse 1992). The same group also suggested major gene control of IL-5 production in the Brazilian *S. mansoni*-infected population (Rodrigues et al. 1996), although whether this is the same gene as that controlling infection intensity remains unclear. A later proposal of a polygenic model would seem more realistic (Bethony et al. 2002). The first genome scan for a human parasitic disease was carried out on the intensity of *S. mansoni* infection using parametric linkage analysis with the model of inheritance defined by segregation analysis of the same population (Marquet et al. 1996). There was strong evidence for linkage to the chromosome cluster at 5q31–q33, with a multipoint LOD score of 5.45. The nearest locus was *CSF1R*. Finding a single region in a genome scan indicates the limitations of this parametric approach and re-analysis of these data using model-free linkage analysis found suggestive evidence for linkage to two further regions on 1p21–q23 and 6p21–q21 (Zinn-Justin et al. 2001). Confirmation of the importance of 5q31–q33 has come from another linkage study of a Senegalese population (Muller-Myhsok et al. 1997). There is less evidence of genetic control of hepatic morbidity resulting from infection with *S. mansoni* (Kariuki et al. 2001); however, this may partly result from variable definitions of severe disease, and pedigree clustering has been observed (Mohamed-Ali et al. 1999). Segregation analysis indicated a co-dominant major gene (*SM2*) controlling advanced hepatic periportal fibrosis in Sudanese *S. mansoni*-infected patients (Dessein et al. 1999). Examination of four candidate loci found evidence of linkage (multipoint LOD score 3.12) to *IFNGR1* at 6q22–q23 (Dessein et al. 1999).

A number of studies have been carried out on HLA control of infection or disease in schistosomiasis. Many of the studies are small and there is some lack of consistency in allelic associations. Early studies concerned HLA control of proliferative responses to *S. japonicum* antigens (Ohta et al. 1982; Hirayama et al. 1987). These were accompanied by an observed increase in *HLA-B40* in high responders to schistosomal antigens and hepatosplenic patients (Ohta et al. 1987). Recent studies on *S. japonicum* are devoted to HLA class II associations and advanced disease/fibrosis (Hirayama et al. 1998, 1999; Waine et al. 1998; McManus et al. 2001). Despite some inconsistencies, one interesting suggestion, from an examination of class II haplotypic associations, is that *HLA-DR* and *HLA-DQ* loci may influence early liver changes, whereas the *HLA-DP* locus may be more important in the later phase (Hirayama et al. 1999). HLA class I associations for hepatosplenic disease, caused by *S. mansoni*, in Egyptian populations vary (Abdel-Salam et al. 1986; Hafez et al. 1991). *HLA-DQB1*0201* was positively associated with hepatosplenic disease in Brazilian patients aged over 15 years (Secor et al. 1996), but not in an Egyptian population (Hafez et al. 1991). A study specifically examining the role of *HLA-DP* showed *HLA-DPA1*0301* to be associated with schistosomiasis and a high re-infection rate after treatment (May et al. 1998).

CONCLUSION

At the time of writing, there is good evidence for genetic control of major viral, bacterial, protozoal, and helminth infections. There are indications of some of the regions involved from linkage studies, in particular from genome scans for several major infections. There are many more association studies for candidate genes, a good proportion of which concern the MHC. The scope of studies is often limited, with insufficient sample sizes and limited polymorphisms investigated. Many findings remain to be replicated, which suggests that there may be many false positives or considerable population heterogeneity. It will be interesting to include information on pathogen diversity in future studies. Moreover

there is little understanding of the impact of genetic diversity on immune function. In this respect, knowledge of complex haplotypes in relation to disease susceptibility and immune function is an immediate goal.

Viral interference with the host immune response

ANTONIO ALCAMI, ANN B. HILL, AND ULRICH H. KOSZINOWSKI

Introduction	1	Effects on the adaptive immune response	14
Effects on molecules that signal between cells	2	Conclusions	23
Apoptosis	7	Acknowledgments	24
Cellular effector cells of innate immunity	11	References	24

INTRODUCTION

The clearance of viruses from infected tissues requires a coordinated scenario of multiple effector functions. The immune response with its two arms of innate and adaptive immune responses represents the system by which the organism controls, preserves, and restores integrity. Clearing of the infection can often cause a substantial loss of cells with little functional impairment as a result of cellular regeneration. In the absence of cellular regeneration, e.g. in the central nervous system (CNS), the same loss may already result in considerable functional defects. Whether or not the immunological clearing of a virus infection protects tissues or causes pathology is defined by the speed and amount of virus replication, the strength of the immune response, and the properties of the infected tissues. Therefore, the outcome of either immunoprotection or immunopathology is defined by properties of the virus, the strength of the immune response and by the regenerative activity of the tissues (Levine 2002). Remarkably, viral immune evasion mechanisms target and modulate all aspects of the innate and the adaptive immune response. To discuss the functional relevance of the different viral function it should be recollected that host defense against viruses occurs in a series of waves.

Cells monitor their normal state and many of the effects of viruses on the intracellular milieu tend to activate the process of apoptosis or programmed cell death. This 'suicide' response can be considered a form of host defense, and most viruses seem to need to interfere with this response in order to be able to replicate. The innate immune response starts with the release of soluble mediators of inflammation. These mediators comprise, among others, the interferons, cytokines, chemokines, complement fragments, prostaglandins, and nitric oxide. These key regulators control cell trafficking and cell recruitment to inflamed sites, cell adhesion, and cell activation, but also induce apoptosis. Different cells produce different mediators. Usually, the organism seeks to eliminate the virus completely and the antiviral activities of some soluble mediators are very potent. However, the life cycle of some viruses, in particular those that establish persistent infections, is more complex and for them the evasion of innate immunity is important to reach the target tissues from which the virus cannot be cleared. Among other viruses the well-known hepatitis viruses B and C, human immunodeficiency virus (HIV), and herpesviruses share this property.

In the temporal scenario of the immune response natural killer (NK) cells form the second line of defense. NK cells play a major role in the early defense to viruses. They do not require prior sensitization to recognize and to kill virus-infected cells. The response is induced within hours of infection and usually peaks around 3 days. Herpesviruses, for example, are very

sensitive to the control by NK cells and the molecules by which these viruses defend themselves against this strong effector mechanism of innate immunity today are the subject of active research.

The third wave includes adaptive immune responses which comprise cellular and humoral effector arms. Important cellular effectors are CD8 and CD4 T cells: these are first detectable at days 3–4, and usually peak at about 7 days. CD8 T cells play the critical role and in most cases are able to eliminate the virus. It was noticed first that viruses manage to escape the control of T cells by various molecular principles and this area of research has brought several interesting findings that reshape our understanding of the virus–host balance.

In the antibody response initially immunoglobulin IgM appears about 10 days postinfection, followed by IgG. Antibody plays some role in controlling primary infection but its main role is to prevent reinfection (by neutralization). Antibody effects can be mediated by complement activation. Even the antibody response and complement are diverted by some viruses to their profit.

EFFECTS ON MOLECULES THAT SIGNAL BETWEEN CELLS

Modulation of interferon functions

Interferons (IFN) were discovered because of their ability to protect cells from viral infection. The key role of both type I (α and β) and type II (γ) IFN as one of the first antiviral defense mechanisms is highlighted by the fact that anti-IFN strategies are present in most viruses (Figure 1).

Interferons are produced in response to viral infection, secreted from cells, and bind specific receptors that trigger intracellular events through Janus kinase (JAK) and signal transducers and activators of transcription (STAT) pathways (Goodbourn et al. 2000). These signaling events result in the upregulation of cellular proteins that limit viral replication in several ways. Some of the genes upregulated by IFN are the low-molecular-weight protein (LMP)-2 and LMP-7 subunits of the proteasome, involved in the generation of viral peptides

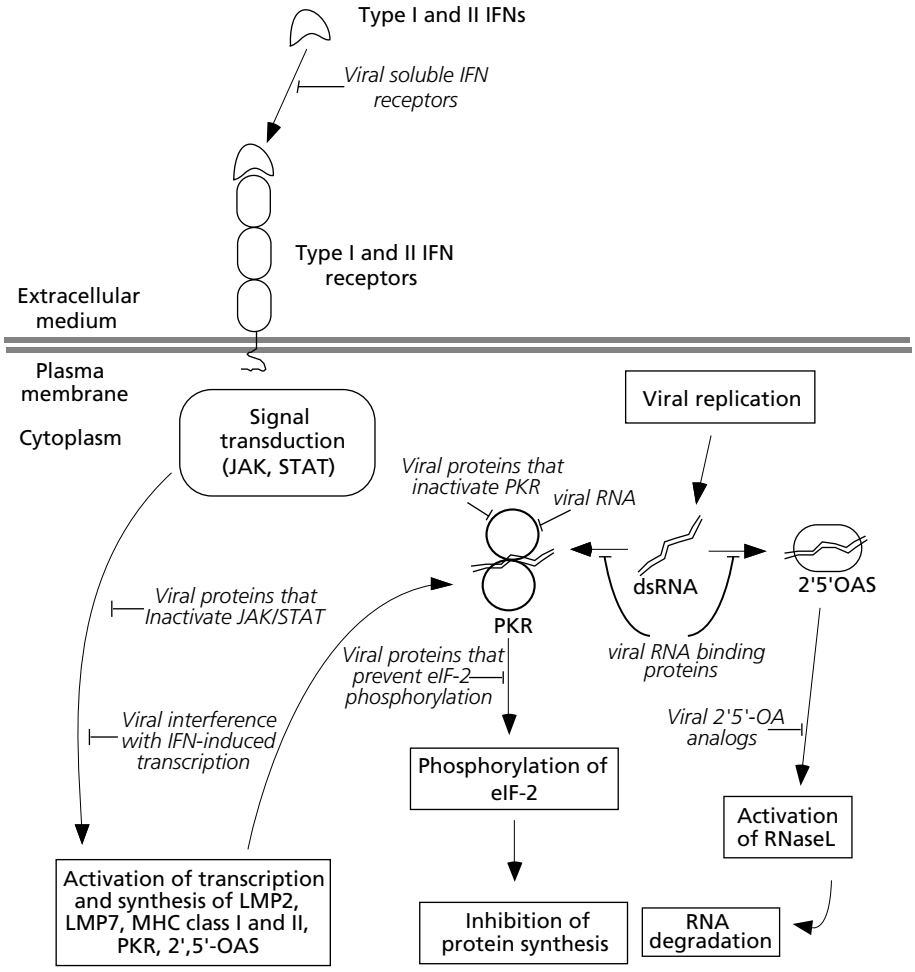

Figure 1 *Viral inhibition of interferon activity. See text for abbreviations.*

for the major histocompatibility complex (MHC) class I and class II molecules, the molecules that present viral peptides to T cells. Two major pathways that induce an antiviral state in cells are also upregulated by IFN: the double-stranded ribonucleic acid (RNA) (dsRNA)-dependent protein kinase (PKR) and the 2′,5′-oligoadenylate system (2′,5′-OAS) that activates RNase L. In addition, IFNs have immunomodulatory activity that can influence the type of immune response mounted as a reaction to infection.

Viruses block the activity of IFNs at three different levels: (1) blockade of IFN binding to specific receptors; (2) inhibition of signal transduction pathways induced by IFNs; and (3) inhibition of antiviral effector functions induced by IFNs (see Figure 1).

SECRETED VIRAL IFN RECEPTORS AND IFN-BINDING PROTEINS

Poxviruses encode proteins that are secreted from infected cells and bind with high affinity type I or II IFN (McFadden and Murphy 2000; Alcami 2003). These proteins prevent the interaction of IFNs with their receptors and the initiation of biological effects that lead to an antiviral state in the cell. Soluble cytokine receptors or binding proteins for other cytokines have been identified, mainly in the poxvirus family, and examples are discussed below.

The viral IFN-γ receptor (vIFN-γR) was first identified in myxoma virus (MV) and later in other members of the poxvirus family including vaccinia virus (VV) and cowpox virus (CV) (Upton et al. 1992; Alcami and Smith 1995; Mossman et al. 1995). The vIFN-γR has sequence similarity to the IFN-binding domain of the cellular IFN-γ receptor. In addition, VV and other poxviruses also encode a secreted IFN-α/β receptor or binding protein (vIFN-α/βBP) that has very limited sequence similarity to the cellular counterparts (Colamonici et al. 1995; Symons et al. 1995). The vIFN-α/βR has the unique property of binding to the cell surface after secretion (Alcami et al. 2000). This property allows the vIFN-α/βR to cover infected tissues with decoy receptors that prevent in a very efficient way the activation of IFN-mediated pathways. The role of vIFN-γR and vIFN-α/βBP during viral infection has been demonstrated by the attenuated phenotype of VV and MV mutants lacking these IFN inhibitors (Symons et al. 1995; Mossman et al. 1996).

INTERFERENCE WITH IFN SIGNALING

Some viral proteins interfere with the signaling cascade initiated in cells by the interaction of IFN with their receptors, and prevent the activation of antiviral mechanisms that limit viral replication (Goodbourn et al. 2000), e.g. the T antigen of murine polyoma virus binds to and inactivates JAK1 (Weihua et al. 1998), whereas protein V from simian virus 5 interacts with STAT1 and induces its degradation by the proteasome (Didcock et al. 1999). A different mechanism is used by Kaposi's sarcoma-associated herpesvirus (KSHV), a virus that encodes a homolog of the IFN-regulatory factor (IRF) which represses the IFN-mediated transcriptional activation of host genes (Zimring et al. 1998).

VIRAL MODULATION OF IFN EFFECTOR FUNCTIONS

One of the major antiviral effects of IFNs is the induction of the dsRNA-dependent PKR and 2′,5′-OAS pathways which lead to the blockade of gene expression in the cell and prevent the formation of infectious virus particles (Goodbourn et al. 2000). The replication and transcription of viral genomes can lead to the formation of double-stranded RNA (dsRNA) that activates PKR, which phosphorylates the translation initiation factor 2α (eIF-2α), causing its inactivation and the subsequent arrest of protein synthesis in infected cells. Viruses use several strategies to inhibit the activity of PKR (Gale and Katze 1998; Katze et al. 2002). Some viruses encode proteins that bind dsRNA and prevent activation of PKR, such as the VV E3L and reovirus σ3 proteins. Adenovirus and HIV encode RNAs that bind PKR but do not activate the enzyme, whereas herpes simplex virus (HSV) US11 and HIV Tat bind directly to PKR and inactivate the enzyme. An alternate strategy to block the PKR pathway is to prevent the phosphorylation of eIF-2α. This can be achieved by the expression of an eIF-2α homolog, the K3L protein of VV, which acts as a substrate of PKR, or by HSV IC34.5 protein-activating protein phosphatase 1α which removes the phosphate groups from eIF-2α. The formation of dsRNA during viral replication also activates the enzyme 2′,5′-OAS, producing 2′,5′-OA which in turn activates RNase L and the degradation of RNA within the infected cell, causing the blockade of viral replication. The synthesis of analogs of 2′,5′-OA by HSV, which bind RNase L, inhibits this pathway (Goodbourn et al. 2000). The proteins σ3 from reovirus and E3L from VV bind dsRNA and thus inhibit the activation of 2′,5′-OAS as well as PKR (see above).

Modulation of cytokine networks

Cytokines constitute a numerous family of molecules that play an important role in the initiation and regulation of the immune response. Cytokines are normally secreted from cells, although some are expressed at the cell surface, and bind to specific receptors on other cells. In this way, cytokines are used by the immune system to communicate among cells and to send signals that drive the immune response in a particular direction. In addition, some cytokines such as IFN and tumor necrosis factor (TNF) may act directly on infected cells and restrict virus replication.

The importance of cytokines in antiviral defense is highlighted by the number of mechanisms that viruses encode to block the activity of cytokines. The viral anticytokine strategies will normally result in down-regulation of immune responses. However, there are examples in which these viral mechanisms increase viral replication. Large DNA viruses such as poxviruses and herpesviruses have captured in their genomes genes that encode host cytokines and cytokine receptors (McFadden and Murphy 2000; Alcami 2003). This strategy enables these viruses to interfere with or to exploit cytokine pathways for their own benefit (Figure 2).

VIRAL CYTOKINES

The first viral cytokine identified was the VV epidermal growth factor homologue (VGF). This viral protein activates cell growth and favors viral replication, but an immune-related function has not been ascribed to it (McFadden and Murphy 2000). The first cytokine with immunomodulatory activity found in viruses is the IL-10 homolog (vIL-10) encoded by Epstein–Barr virus (EBV) (Hsu et al. 1990). Genes encoding IL-10 homologs have also been identified in other viruses. It has been shown that the EBV vIL-10 suppresses cellular immunity by inhibiting the production of IFN-γ, but has lost the immunostimulatory properties of the host counterpart. Other viral cytokines are the IL-6 homolog (vIL-6) encoded by KSHV (Moore et al. 1996) and the IL-17 homolog (vIL-17) encoded by herpesvirus Saimiri (HVS) (Yao et al. 1995). These cytokines may have immunomodulatory activity but vIL-6 and vIL-17 may also promote the proliferation of B and T cells, respectively, which represent the major host cell types for these viruses.

The identification of semaphorin homologs (vSEMA) in poxvirus and herpesvirus genomes was somehow surprising because semaphorins were described as chemoattractants and chemorepellents involved in axonal guidance during nervous system development, and only CD100 had been identified as a semaphorin involved in the immune system (Spriggs 1999). The characterization of vSEMA encoded by VV and ectromelia virus (EV) uncovered a specific receptor in macrophages and its proinflammatory activity, which was observed in mice infected with a VV expressing an active vSEMA protein. The precise role of vSEMA in immune modulation during viral infection remains to be determined.

SECRETED VIRAL CYTOKINE RECEPTORS

Viral genes encoding soluble cytokine receptors have been identified mainly in the poxvirus family. These cytokine receptors lack the transmembrane and cytoplasmic domains of the host counterparts, are secreted in large quantities from infected cells, and have the ability to bind with high affinity the cognate cytokine and block its activity. The poxvirus soluble cytokine receptors were initially identified because of their sequence similarity to the extracellular binding domain of their host counterparts. A second class of cytokine receptors, known as binding proteins, have very limited sequence similarity to the host cytokine receptors and were identified in cytokine binding or activity assays.

The first viral cytokine receptor identified was the viral TNF receptor (vTNFR) M-T2 encoded by MV (Smith et al. 1991). Subsequent studies identified four different genes encoding vTNFR in poxviruses such as CPV, VV, and EV, and were designated cytokine response modifier B (CrmB), CrmC, CrmD, and CrmE (Hu et al. 1994; Smith et al. 1996; Loparev et al. 1998; Saraiva and Alcami 2001). CrmB is equivalent to MV M-T2 but the other proteins are distinct with respect to binding properties and molecular size, and are produced at different times during viral replication. The reasons for such a variety of proteins apparently targeting the

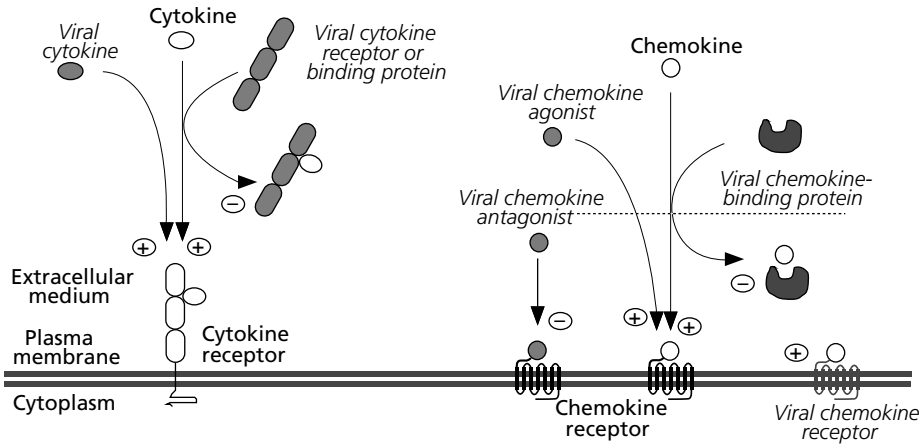

Figure 2 *Viral mimicry of cytokines, chemokines, and their receptors.*

same ligand are unknown. Clinical isolates of human cytomegalovirus (HCMV), but not laboratory strains, encode a membrane TNFR homolog related to herpesvirus entry mediator (HVEM) which is retained intracellularly (Benedict et al. 1999). No ligand has been identified for this protein and its function remains to be determined. More recently, another member of the TNFR superfamily has been identified in CPV and EV. In this case, the viral protein is a secreted and shorter version of human and mouse CD30 (Panus et al. 2002; Saraiva et al. 2002). Viral cytokine receptors function as decoy receptors neutralizing the activity of cytokines and, accordingly, vCD30 blocks the interaction of CD30 to CD30 ligand (CD30L). However, in this case the ligand is expressed only at the cell surface and vCD30 induces reverse signaling in CD30L-expressing cells. The function of vCD30 in the context of infection has not been elucidated, but administration of vCD30 to mice has been shown to downregulate type 1 cytokine-mediated inflammatory responses, a property that may help the virus to escape an efficient antiviral response (Saraiva et al. 2002).

The viral IL-1β receptor (vIL-1βR) is related to the human type II IL-1R and also acts as a decoy receptor (Alcami and Smith 1992; Spriggs et al. 1992). In contrast to the membrane IL-1Rs encoded by the host, the viral protein is specific for IL-1β and does not bind IL-1α or IL-1 receptor antagonist. Deletion of this gene in VV causes attenuation when the virus is administered intracranially (Spriggs et al. 1992), but leads to enhanced virulence associated with fever and accelerated death in mice infected through the respiratory route, a natural route of poxvirus transmission (Alcami and Smith 1992, 1996). The enhanced virulence observed after deletion of the vIL-1βR from VV illustrates that the role of some viral immunomodulatory proteins may be to reduce pathology induced by excess production of cytokines, in this case IL-1β, during infection rather than to cause immunosuppression.

VIRAL CYTOKINE-BINDING PROTEINS

IL-18 is a proinflammatory cytokine that is required, together with IL-12, for induction of IFN-γ and the generation of an efficient cellular response against viral infection. The poxvirus-encoded IL-18 binding protein (vIL-18BP) is a homolog of the human IL-18BP but has no sequence similarity to membrane IL-18 receptors. The vIL-18BP is an effective scavenger of IL-18, and downregulates IFN-γ production and NK responses in EV-infected mice (Born et al. 2000; Smith et al. 2000). Interestingly, the vIL-18BP is also expressed by molluscum contagiosum virus (MCV), a poxvirus that causes benign skin tumors and persists in the skin for months without inducing an inflammatory response (Xiang and Moss 1999; Smith et al. 2000). The vIL-18BP is the only cytokine receptor encoded by MCV and may be responsible in part for the lack of inflammation in MCV lesions.

The only soluble cytokine-binding protein identified in herpesvirus is encoded by EBV and binds colony-stimulating factor (vCSF-1BP) (Strockbine et al. 1998). This protein has limited sequence similarity to the cellular receptor and may modulate the response of macrophages during infection. Another example of a viral cytokine-binding protein that binds ligands using different host receptors is a secreted protein that binds granulocyte–macrophage-CSF and IL-2 encoded by orf virus, a virus that causes skin lesions in sheep, goats, and humans (Deane et al. 2000).

Modulation of chemokine networks

Chemokines are a family of small-molecular-size cytokines that induce cell migration and other biological effects, such as cell differentiation and angiogenesis, and play a critical role in the regulation of cells of the immune system throughout the body. There are more than 40 chemokines identified that can be structurally classified as CC, CXC, C, or CX3C, and mediate their biological response by binding and signaling through G-protein-coupled receptors, proteins that have seven-transmembrane domains. More than 20 chemokine receptors have been identified and their distribution in immune cells determines which type of cell migrates in response to infection or inflammation. There are three structural concepts used by viruses, mainly herpesviruses and poxviruses, to modulate chemokine activity: expression of chemokine homologs, chemokine receptor homologs, and secreted chemokine-binding proteins unrelated to the sequence of known host receptor proteins (McFadden and Murphy 2000; Murphy 2001; Alcami 2003)

VIRAL CHEMOKINE HOMOLOGS

The virus-encoded chemokine homologs are secreted from infected cells and function as agonists or antagonists. Chemokine antagonists such as vMIP-II from KSHV and MC148 from MCV, bind to chemokine receptors but do not transduce signals (Boshoff et al. 1997; Kledal et al. 1997; Krathwohl et al. 1997; Damon et al. 1998). These antagonists function as inhibitors of specific chemokine pathways and influence the migration of immune cells into infected tissues. By contrast, the viral chemokine agonists induce cell migration into areas of infection, and thus their function may be unrelated to immune evasion. The current thinking is that viral chemokine agonists recruit to areas of infection immune cells that represent good targets for viral replication and enhance viral dissemination. The chemokine encoded by the gene *UL146* from HCMV, known as vCXC-1, induces neutrophil chemotaxis by binding to CXCR2

and may explain the association of neutrophils with HCMV infections (Penfold et al. 1999). Human herpesvirus 6 (HHV-6) U83 induces monocyte migration that may favor the establishment of viral latency and persistence in the infected host (Zou et al. 1999). Another example of chemokine mimetics is the protein Tat from HIV which shows limited sequence similarity to chemokines. HIV Tat is a chemoattractant for monocytes and may enhance replication and spread of HIV in infected individuals (Albini et al. 1998). Direct evidence for a role of viral chemokine agonists in vivo comes from studies with murine cytomegalovirus (MCMV) mutants lacking the chemokine genes *M131/129*. The MCMV chemokine is encoded by the *m131orf* and is expressed as a fusion protein including the *m129 orf*. The isolated synthetic *m131* product attracts activated macrophages by engaging a receptor with structural properties related to human CCR3 (Saederup et al. 1999). The mutant MCMV lacking the function shows reduced spread to salivary glands, indicating that monocyte attraction serves for virus trafficking.

The role of the viral chemokines encoded by KSHV in viral dissemination has not been defined but they may play a role in pathogenesis as a result of their angiogenic properties which may cause the enhanced vascularization observed in Kaposi's sarcoma lesions (Boshoff et al. 1997). In addition, the KSHV chemokines are chemoattractants for Th2-polarized T cells and may influence the type of immune response initiated after viral infection (Sozzani et al. 1998; Dairaghi et al. 1999; Endres et al. 1999; Stine et al. 2000).

An interesting and recent addition to chemokine mimicry by viruses is the finding that glycoprotein G (gG) of respiratory syncytial virus has partial sequence similarity to fractalkine and has chemokine-like activity (Tripp et al. 2001). This property of gG may be used to facilitate virus attachment to infected cells and to modulate the host immune response.

VIRAL CHEMOKINE RECEPTOR HOMOLOGS

There are several examples of chemokine receptor homologs in members of the herpesvirus family and some in the poxvirus family. The function of these receptors in the viral infectious cycle is varied and difficult to demonstrate. Some viral chemokine receptors bind chemokines and transduce signals inside the cell. The ORF74 protein from KSHV is constitutively active and binding of chemokines can modulate the activation status of the receptor (Arvanitakis et al. 1997; Rosenkilde et al. 1999). The receptor has been shown to induce cell proliferation when expressed in cells in culture and its expression in transgenic mice causes the development of Kaposi's sarcoma-like lesions (Arvanitakis et al. 1997; Yang et al. 2000). The possibility that expression of KSHV ORF74 may contribute to neoplasia through a paracrine effect has been proposed, but may be difficult to demonstrate in KSHV-infected individuals. In any case, ORF74 illustrates how such proteins encoded by viruses may have a direct and profound effect on the pathology caused by viral infection. In vivo studies on the homologous ORF 74 encoded by murine γ-herpesvirus 68 (MHV-68) have revealed that the virus uses this receptor for virus reactivation from latently infected mouse splenocytes (Lee et al. 2003). Of the four chemokine receptor homologs encoded by HCMV, UL78, UL33, US27, and US28, US28 is most extensively studied. MCMV encodes the viral chemokine receptor (vCKR) M33 and M78, which are homologous to their counterparts in HCMV. HCMV US28 can modify the chemokine environment of infected cells by sequestering and internalizing chemokines, and depleting them from the medium (Bodaghi et al. 1998). Similarly, HHV-6 UL51 reduces extracellular accumulation of chemokines by sequestration, but also by a novel mechanism of downregulation of CCL5 (RANTES) transcription (Milne et al. 2000). The potential contribution of viral chemokine receptors to pathology is also illustrated by the fact that HCMV US28 expression on the cell surface mediates cell adhesion and vascular smooth muscle cell migration, and it is thought to be related to vascular disease (Streblow et al. 1999). Evidence for a role for viral chemokine receptors in virus replication in vivo was demonstrated first for MCMV M33 (Davis-Poynter et al. 1997).

VIRAL CHEMOKINE-BINDING PROTEINS

The third class of viral chemokine inhibitors are the viral chemokine-binding proteins (vCKBP) that sequester chemokines in solution without apparent sequence similarity to host chemokine receptors. These proteins were initially described in poxviruses, but an example has been identified recently in the herpesvirus family.

The MV M-T7 (vCKBP-1) is a soluble vIFN-γR with sequence similarity to human IFN receptors but was later found to interact with chemokines. MV M-T7 binds a broad spectrum of chemokines and it has been proposed that it prevents the interaction of chemokines with glycosaminoglycans (GAG) and the correct presentation of chemokines to leukocytes (Lalani et al. 1997). There is evidence that the interaction of chemokines with cell-surface GAGs is important for their function in vivo. The protein vCKBP-2 was identified in the medium from cultures infected with MV, VV, or CPV (Graham et al. 1997; Smith et al. 1997; Alcami et al. 1998). In this case, the protein binds CC chemokines with high affinity and neutralizes their effect by preventing the binding of chemokines to specific receptors in leukocytes. The protein M3 (vCKBP-3) encoded by murine MHV-68 was found to bind a broad range of chemokines, including C, CC, CXC, and CX3C chemokines, and to

block their interaction with cellular receptors (Parry et al. 2000; van Berkel et al. 2000).

The generation of relevant virus mutants lacking specific vCKBPs and the infection of rabbits or mice suggest that these proteins may block chemokine-mediated leukocyte infiltration into infected areas in vivo (Mossman et al. 1996; Graham et al. 1997; Lalani et al. 1997). In addition, MHV-68 M3 has been proposed to be required by the virus to establish virus latency and to enable persistence of the virus in the host (Bridgeman et al. 2001). Sequestration of chemokines can also prevent the process of dendritic cell (DC) maturation and trafficking (see below).

VIRAL MODULATION OF CYTOKINE EXPRESSION AND ACTIVATION

Other mechanisms that modulate the synthesis of cytokines and the signaling cascade triggered by them have been described. The expression of cytokines mediated by the nuclear factor κB (NF-κB) and nuclear factor-activated T cell (NFAT) transcription factors in macrophages is blocked by an IκB homolog encoded by African swine fever virus (Miskin et al. 1998). The CPV protein CrmA was found to inhibit the IL-1β-converting enzyme (ICE) (or caspase-1), which proteolytically cleaves the precursor form of proinflammatory cytokine IL-1β (pro-IL-1β) to generate mature, active IL-1β (Ray et al. 1992). CPV CrmA may also prevent the maturation of IL-18, which is also proteolytically cleaved by ICE, and is an inhibitor of apoptosis (see below under Viral inhibitors of caspases).

There are several examples of viruses that inhibit cytokine-mediated signaling. Adenoviruses interfere with signaling induced by TNF at different levels (Mahr and Gooding 1999), and some herpesviruses and poxviruses inhibit signaling through death domains that lead to apoptosis (see below under Viral inhibitors of death receptor-mediated apoptosis). The poxvirus VV encodes two intracellular proteins that block signaling mediated by Toll-like and IL-1 receptors by mimicking intracellular regulatory domains of these receptors (Bowie et al. 2000). The Toll-like receptor pathway is important in NF-κB activation and amplification of inflammatory signals.

Lastly, some viruses may subvert cytokine-mediated signaling for their own benefit. The latent membrane protein 1 (LMP1) of EBV recruits components of the TNFR and CD40 transduction machinery and induce biological responses such as cell proliferation that may enhance virus replication (Farrell 1998).

APOPTOSIS

Programmed cell death (apoptosis) is a ubiquitous and evolutionarily conserved mode of cell death. Individual cells are eliminated or removed from the organism in a temporal manner or in response to specific signals without affecting neighboring cells. Apoptosis plays a central role in tissue homeostasis throughout life (Rathmell and Thompson 2002). Apoptosis is characterized by loss of cell volume or cell shrinkage, chromatin condensation, internucleosomal DNA fragmentation, phosphatidylserine exposure, membrane blebbing, and the formation of apoptotic bodies. These stereotypical morphological changes, associated with natural death, are based on a highly regulated genetic program. The activation of a class of cysteine proteases, termed 'caspases', as the central effectors plays an essential role. Caspases are synthesized initially as single polypeptide chains representing latent precursors (zymogens) which undergo proteolytic processing at specific aspartic acid residues to produce two distinct subunits that assemble to the active heterotetrameric protease. In mammalian cells, activation of the caspase zymogens has been reported to occur through at least three independent mechanisms: cleavage by upstream active caspases; cleavage by granzyme B, an aspartate-specific serine protease found in the granules of cytolytic T cells; and autoprocessing of zymogens with assistance from other caspase-interacting proteins that can occur in either a *cis*- or *trans*-acting manner (for reviews, see Salvesen and Dixit 1997; Benedict et al. 2002; Bortner and Cidlowski 2002; Trapani and Smyth 2002)

There are several caspases that are functionally redundant. Once activated, one caspase can activate other caspases in the proteolytic cascade (Stennicke et al. 1998). The trigger of the proteolytic cascade involves the physical association of zymogens via adaptor proteins with protein interaction modules that assemble the receptor signaling complex. The apoptotic program in cells includes mechanisms that activate and those that inhibit apoptosis. There are two main pathways of apoptosis.

Death receptor-initiated activation of caspases

Cells can receive extrinsic signals that instruct them to die. The primary receptor through which death signals are signaled are members of the TNFR family, such as Fas and TNFR-1(19,24). Binding of receptor and ligand on the cell surface results in the formation of the hetero-oligomeric death-inducing signal complex (DISC). The apoptosis-inducing quality of a death receptor ligand system is defined by the death domain (DD) located in the intracellular portion of the death receptor. The DISC is assembled by complex protein interactions. The DDs and death effector domains (DED) carried by different proteins, e.g. caspases, are essential components. DISC proteins interact with other proteins through homotypic interactions of DD and DED contacts. The basis of the interaction is structural motifs

of the DD which form six antiparallel helical bundles. Adaptor proteins such as FADD contain both a DD and a DED motif in one polypeptide and provide the bridging between DD domains of receptors with a DED-containing caspase. Among the caspases, mainly the initiator caspases-8 and -10 are recruited to the DISC. It is thought that the conformational properties and local concentrations of different proteins in the DISC complex govern caspase activation by autocatalytic processing (Schmitz et al. 2000; Walczak and Sprick 2001).

Mitochondrial pathway of caspase activation

Independent of the extrinsic death receptor pathway, apoptosis is also controlled intrinsically at the level of mitochondria. Mitochondrial death can result from the loss of extracellular vital signals (death by neglect), and by signals affecting the cell cycle, through activation of p53 and the proapoptotic p53 target genes (Rathmell and Thompson 2002). Changes in nutrient uptake, serum withdrawal, the deprivation of cytokines, and other metabolic events that affect the cellular redox potential, or the ability properly to regulate active oxygen species, lead to apoptosis. An important molecule in mitochondrial apoptosis is cytochrome *c*. Cytochrome *c* resides in the space between the inner and outer membranes of the mitochondria. The release of cytochrome *c* initiates mitochondrial apoptosis at the apoptosome, a protein complex called Apaf-1. It consists of the caspase-activating molecules, which can bind to caspase-9 through homotypic interaction via a domain defined as caspase-recruitment domain (CARD). For activation of caspases, Apaf-1 requires cytochrome *c*. A number of signals control the oligomerization of Apaf-1–caspase-9 complexes. Additional proteins that have CARD domains can have opposing activities on apoptosome formation, either inhibition or enhancement.

Procaspase-8 activation can also occur at sites other than the cell surface. BAP-31, an integral protein of the endoplasmic reticulum, can recruit an isoform of procaspase-8, procaspase-8L, containing an N-terminal extension in response to apoptotic signals. This suggests an additional organelle-specific pathway of cell death (Ng et al. 1997; Nguyen et al. 2000; Breckenridge et al. 2002). This pathway is also regulated by the Bcl-2 proteins discussed below (Figure 3).

Cellular regulation of extrinsic apoptosis

The cellular homolog of the viral caspase-8 (FLICE) inhibitory protein (cFLIP) consists of two DED domains and a caspase domain that lacks the enzymatic active site. Therefore, cFLIP can bind but not cleave cellular zymogen substrates. It is spliced in two forms; one form contains only the two DED domains; the other, long form includes the caspase-like domain. In addition, cFLIP may block caspase-8 recruitment to the DISC or may inhibit proteolytic processing of the proenzyme. However, cFLIP can also promote recruitment of caspase-8, which can stimulate autoprocessing to the active form.

REGULATION OF CASPASE ACTIVITY

Regulation of caspase activity is central to the death process (Bortner and Cidlowski 2002). The inhibitor of apoptosis (IAP) family of proteins regulates caspase activation and activity. The first member of the IAP family was found in baculovirus. The cellular proteins with antiapoptotic function share, with the baculovirus protein, the baculoviral IAP repeat (BIR), a domain that consists of about 70 amino acids with conserved spacing of cysteine and histidine residues, which fold into a zinc-binding structure. Through the BIR domain, IAP molecules bind and directly inhibit caspase activation. Several IAPs also contain a ring-finger domain located near the C termini. Through the activity of the ring-finger domains, IAPs can target caspases for ubiquitinylation and degradation. IAPs themselves are again subject to inhibition by other proteins that activate caspases. IAPs can bind to caspases in either the active configuration or the inactive proform state.

REGULATION OF MITOCHONDRIAL APOPTOSIS

The Bcl-2 family of proteins controls the release of proapoptotic proteins from mitochondria. Bcl-2 is present in the outer mitochondrial membrane and Bcl-2-like proteins have pore-forming activities and prevent the release of cytochrome *c*. The Bcl-2 family proteins are characterized by protein domains defined as Bcl-2 homology (BH). Four such domains, BH1–4, have been identified. BCL-2 proteins have up to four BH domains. The α-helical BH3 domain of one protein interacts with a receptor formed by a hydrophobic pocket created by BH1–3 of the other protein. Through BH domains BH2 family members interact with each other and form homo- and heterodimers, which results in the promotion of abrogation of the function of the binding partner. Bcl-2 family members have either proapoptotic or antiapoptotic properties. Many antiapoptotic Bcl-2 family members contain domains BH1, -2, and -4. Proteins that carry only the BH3 domain define a family of proapoptotic proteins. Many death-signaling pathways require one BH3-only protein to activate the Bcl-2 family members BAX and BAK in order to activate the caspase. BAX and BAK are functionally redundant and their overexpression leads to mitochondrial accumulation of the protein and initiation of apoptosis. BAK-type proteins make the mitochondrial membrane permeable so that it releases intermembrane apoptogenic factors.

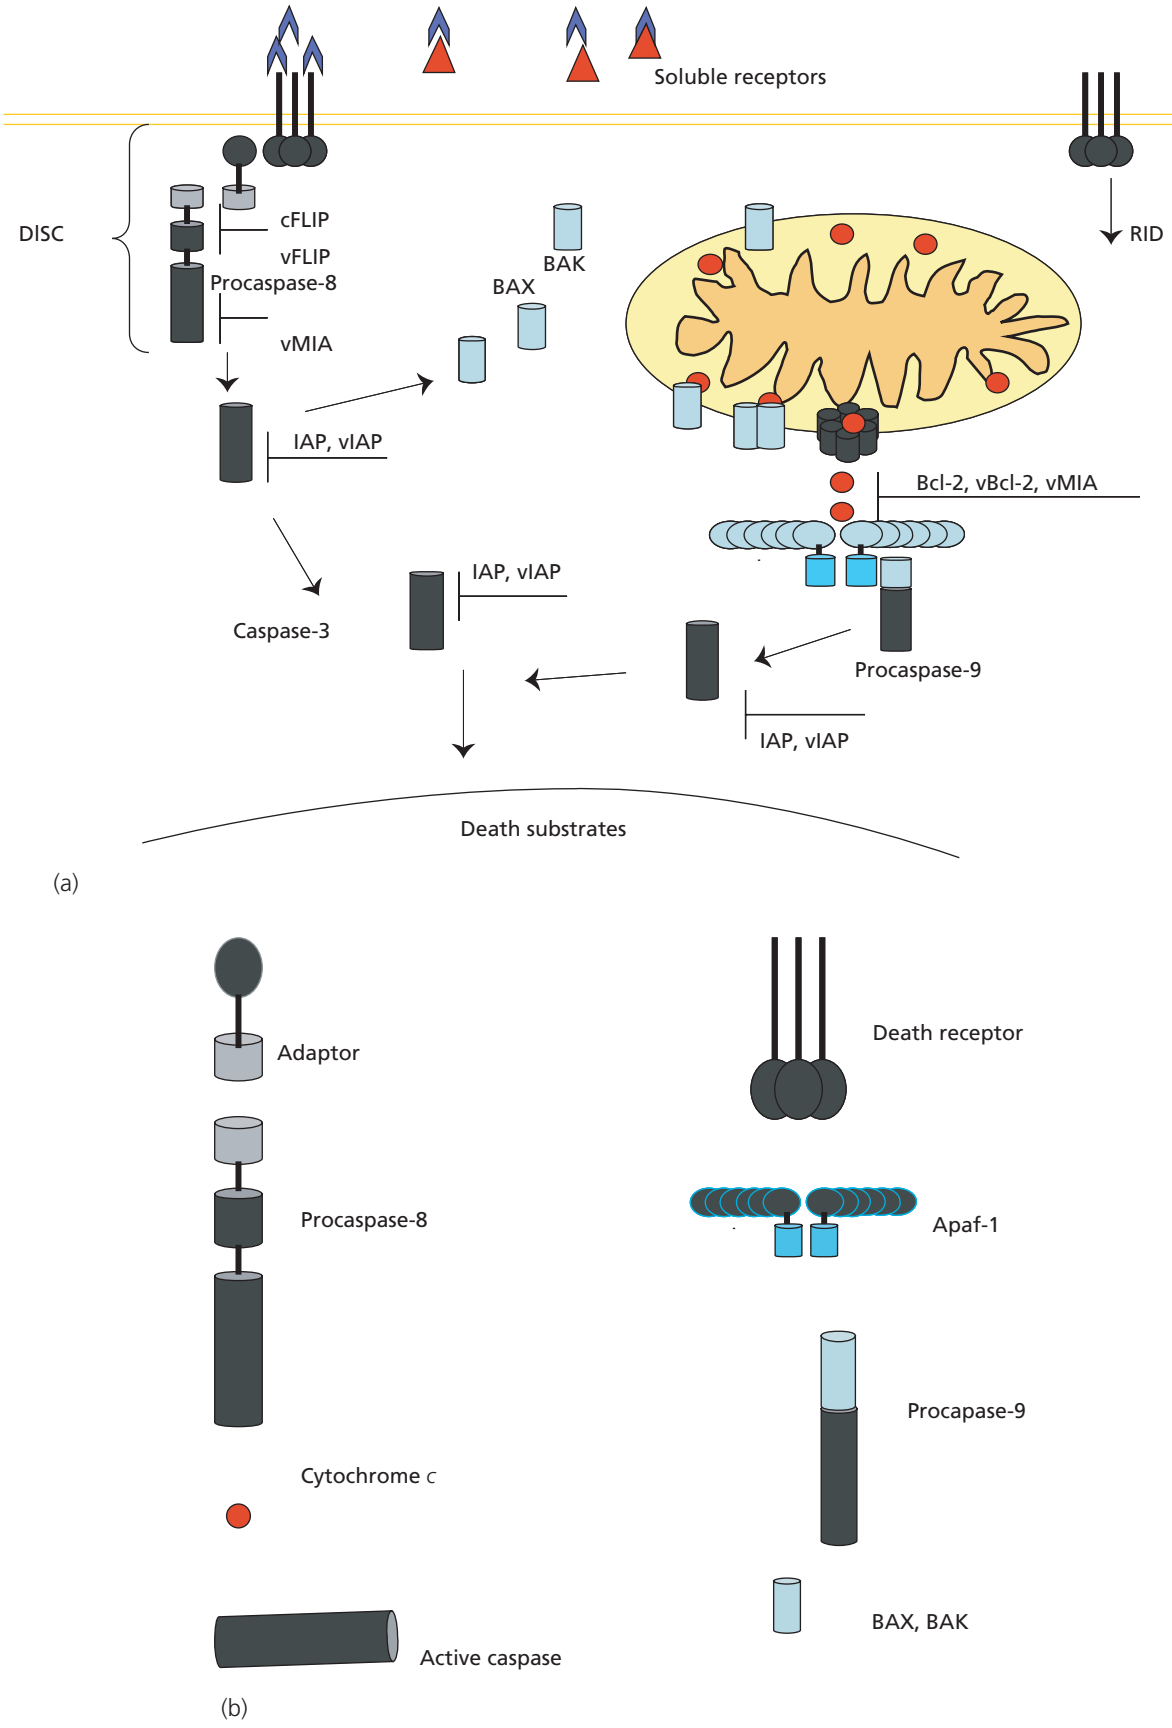

Figure 3 *Viral regulation of apoptosis. See text for abbreviations.*

BAX is primarily cytoplasmic but translocates to mitochondria on apoptotic stimuli. Specific conformational alterations of BAX allow mitochondrial docking. Like BAX, BAK has a transmembrane domain and is targeted to mitochondria where it exists as a monomer or in a complex with other Bcl-2 family members. Antiapoptotic Bcl-2 family proteins bind and inhibit the proapoptotic proteins.

CELLS DIFFER IN APOPTOSIS REGULATION

Cell lines differ with respect to the preferential usage of the two signaling pathways leading to apoptosis. Type 1 cells constitutively contain a large amount of caspases at the DISC. Fas triggering results in caspase-8 activation, followed by cleavage of caspase-3 and loss of the mitochondrial transmembrane potential. In type 2 cells, there is little DISC formation and the intrinsic mitochondrial pathway is required as an amplifier to initiate the full apoptosis cascade after Fas activation. Only in type 2 cells can apoptosis triggered by extrinsic signals be blocked by BCL-2 overexpression. Apoptosis in type 2 cells is dependent on the activities of mitochondria, whereas apoptosis in type 1 cells is not. T cells have type 1 and liver cells have type 2 characteristics (Scaffidi et al. 1998).

Chaperones and chaperone-like proteins that support the folding of newly synthesized proteins can also have pro- and antiapoptotic functions. Heat shock protein (HSP) 70-like chaperones inhibit apoptosis, whereas HSP-60 and HSP-10 have proapoptotic functions. Likewise, protein kinases modulate apoptosis. Mitogen-activated kinases (MAPK) control apoptosis through transcription, e.g. the upregulation of cFLIP, and also through transcription-independent mechanisms.

Viral control of apoptosis

Replication for viruses, as obligatory intracellular parasites, is dependent on cellular function. Therefore, for virus replication it is important that apoptosis triggered by soluble mediators of innate immunity via death receptors and caspase cascades is inhibited. The viral replication machinery diverts and exhausts cellular functions. Thus, viral protein synthesis, viral morphogenesis, and viral release must destabilize the homeostasis and integrity of the cell. This results in the activation of the intrinsic pathway of apoptosis. For effective viral progeny generation, it is important to delay this process. Some viruses also have proapoptotic properties, which may contribute to the release of virus particles from the cell that is already depleted from its resources. The execution of a proapoptotic function may also be advantageous, if apoptosis of an infected cell causes phagocytosis by another cell and enables the virus transfer to cells that the virus cannot infect directly. Therefore, it is not surprising that viruses may contain both antiapoptotic and proapoptotic functions. Some of the viral genes controlling apoptosis are derived from the host cell genome; for others there are no known homologs. NK and T-effector cells have two important functions: they kill infected cells through the perforin/granzyme pathway or by engaging fas, and they secrete several cytokines, among which IFN-γ is known to be essential for control of virus in some situations. Both pathways of cytolysis induce apoptosis of targets. The viral antiapoptotic functions may play a role in diminishing effector cell efficacy, but caution is warranted before making this assumption. Virus-infected cells are generally readily lysed by T cells, so long as the T-cell receptor (TCR) is triggered, in spite of the presence of antiapoptotic mechanisms. It is likely that the strength of the death signal imposed, particularly by the perforin/granzyme pathway, is able to overcome most antiapoptotic mechanisms.

VIRAL INHIBITORS OF DEATH RECEPTOR-MEDIATED APOPTOSIS

Poxviruses secrete proteins that bind to cytokines, which in turn activate death receptor-mediated apoptosis. This probably represents the earliest possible defense against apoptosis signals. The expression of the death receptor CD95 is inhibited by viral IFN regulatory factors from HHV-8 that inhibit the binding of IFN-γ induced IFN regulatory factor 1 (IRF-1) to specific domains in the CD95L promoter (Kirchhoff et al. 2002). The functions of adenovirus interfere with the apoptosis mediated by the TNF receptor superfamily at a very early stage and at various levels (Burgert et al. 2002; McNees and Gooding 2002). Post-translational downregulation of FAS is carried out by the E3/10.4K–E3/14.5K protein complex, also named receptor internalization (RID) and degradation, together with the E3/6.7K protein. The RID complex contains transport motifs in the cytoplasmic tail of the proteins which are recognized by the intracellular transport machinery that directs the CD 95/RID complex to lysosomes. Apart from CD95, the TNF-related apoptosis-inducing ligand (TRAIL) receptor can form a death-inducing signaling complex. In addition TRAIL receptors are downregulated by the E3 proteins of adenovirus.

The DISC is the next target for modulatory viral proteins. It is assembled by protein interaction between DDs and DEDs. Search for proteins carrying homology to DEDs led to the identification of viral proteins with two DEDs (Derfuss and Meinl 2002). These viral proteins block the activation of caspase-8 (FLICE) and were therefore named viral FLICE inhibitor proteins (vFLIPs). These vFLIPs have been detected in poxvirus and several herpesvirus genomes. In addition, vFLIPs regulate the expression of transcription factors for proteins involved in apoptosis regulation. The product of

the HCMV gene, *UL36 vICA*, binds procaspase-8 but lacks homology to cFLIP (Goldmacher 2002).

VIRAL INHIBITORS OF CASPASES

The archetypal member of the cellular IAP family was found in baculovirus. Through the BIR, a motif that can be present up to three times, IAP molecules bind and directly inhibit caspase activation. Other caspase inhibitors are the poxvirus serine protease inhibitor CrmA (which targets a number of caspases) and related proteins from other poxviruses and African swine fever virus, and p35 of baculovirus. Interestingly, viral proteins can combine IAP properties with properties of BCL-2 protein functions (Wang et al. 2002b).

VIRAL INHIBITORS OF MITOCHONDRIAL APOPTOSIS

Prevention of mitochondrial permeabilization is essential for the replication of many viruses. Many γ-herpesviruses encode one or more molecular homologs of BCL-2, the cellular antiapoptotic protein family (Cuconati and White 2002). Viral BCL-2 homologs are also found in adenovirus and poxvirus genomes. Viral BCL-2 proteins act as apoptosis inhibitors and their structure is similar to that of the cellular BLC-2 proteins. However, despite the preservation of the overall structure the unstructured loops that encode sites for phosphorylation and proteolysis, and which may be required for regulation, the function of the cellular proteins differs between vBCL-2 and cellular BCL-2 proteins. All vBCL-2s have a BH1 and at least one other BH2 or BH3 region. Mitochondrial apoptosis is a limiting factor in the life cycle of DNA viruses, because in cells deficient in BAX and BAK the onset of cytopathic effects is delayed and more viral replication can occur. In adenovirus the E1-B19K inhibits the formation of the highly oligomeric BAX/BAK complex at the mitochondrial membrane.

The viral mitochondrial localized inhibitor of apoptosis encoded by HCMV (vMIA) also targets mitochondria but acts differently from the viral BCL-2 homologs (Goldmacher 2002). It has no BCL-2 homology domains and has no affinity to BAX. However, vMIA forms a complex with adenine nucleotide translocator (ANT), a component of the mitochondrial transition pore complex, which cooperates with BAX in the mitochondrial control of apoptosis (Marzo et al. 1998).

CELLULAR EFFECTOR CELLS OF INNATE IMMUNITY

Natural killer cells, effector cells of innate immunity

Natural killer cells are large granular lymphocytes that have potent antiviral effector mechanisms: they kill infected cells using the perforin/granzyme pathway, and release copious amounts of IFN-γ. In many virus infections, viral titers start to decline as a result of NK function well before the adaptive CD8 immune response has any effect. Unlike T cells, NK cells do not have clonally expressed antigen receptors with specificity for viral peptides. Instead, they use a series of germline-encoded receptors to detect the consequences of virus infection on cells, irrespective of the antigenic composition of the infecting virus. Some of these receptors are activating, and some are inhibitory. Signals from these receptors are integrated, leading either to killing and release of IFN, or no action.

For NK cells to control virus, they need (1) to be induced, (2) to traffic to the site of virus infection, (3) to be able to detect virus-infected cells, and (4) to perform their effector functions (killing cells and releasing IFN-γ). Discussion of interference with NK cells is usually limited to the third step – NK recognition of infected cells. NK trafficking and effector mechanisms are very similar to those of CD8 T cells, and are discussed below. NK cells are induced by cytokines – particularly type I interferons and IL-12, which are produced by infected tissues, and viral interference with production of those cytokines affects the NK response.

Natural killer cells integrate signals from activating and inhibitory receptors to achieve activation threshold (Colonna et al. 1999; Fong and Cambier 1999; Long 1999; Ravetch and Lanier 2000; Lanier 2001). It is likely that not all of these receptors and their ligands have been identified. Two important activating receptors are known: CD16 is an Fc receptor that enables NK cells to lyse cells with bound antibody, a process known as antibody-dependent cell-mediated cytotoxicity (ADCC) (see below under Inhibition of humoral immunity). ADCC is not generally considered to play a major role in antiviral immunity, and obviously plays no role in the NK control of the first few days of infection.

A second major activating receptor – NKG2D – has recently been described (Bauer et al. 1999; Wu et al. 1999). NKG2D is a C-type lectin that homodimerizes to generate a functional receptor. Most NK cells express NKG2D, making it an important activating receptor. Through a positively charged residue in its transmembrane domain, it interacts with the immunoreceptor tyrosine based activation motif (ITAM)-containing DAP10, to deliver a strong activating signal to the cell. In addition to NK cells, NKG2D is expressed on activated classic CD8 T cells and on γδ T cells: for these cells, it acts as a costimulatory molecule, i.e. signaling through NKG2D is not enough to activate the cell. For NK cells, however, NKG2D signaling is sufficient for activation. The ligands for NKG2D show loose homology to MHC class I. It is not yet clear whether all ligands have been identified, and the main ligands are different for humans and mice. In humans, MICA and MICB are stress-inducible molecules

expressed mainly in epithelial tissues, and, interestingly, by most carcinomas (Bauer et al. 1999). MIC expression is induced by HCMV infection (Groh et al. 2001). A second set of receptors are the UL16-binding proteins (ULBP), discovered as the targets for HCMV *UL16* (see below) (McNees and Gooding 2002). The ULBP are homologous to one set of murine ligands for NKG2D – the retinoic acid early inducibles (RAE). The other known murine ligand is H60, a minor histocompatibility antigen expressed in BALB/c mice (Diefenbach et al. 2000)

There are two families of inhibitory receptors for human NK cells: the killer immunoglobulin-like receptors (KIR) and the C-type lectin NKG2A/CD94 paired heterodimer. The KIR are members of the immunoglobulin superfamily, and are encoded in a locus on chromosome 19 (Vilches and Parham 2002). They interact with classical MHC class 1 molecules, different members having different specificities. In particular, important inhibitory KIR recognize a limited polymorphism on HLA-C and HLA-B molecules. KIR are expressed on subsets of NK cells; one theory of NK cell development suggests that during their education NK cells must express at least one inhibitory receptor capable of recognizing self-MHC. NKG2A/CD94 interacts with HLA-E, a nonpolymorphic class I molecule that binds peptides derived from the leader sequence of classic MHCI molecules (Braud et al. 1998a). Murine NK cells also have two families of inhibitory receptors. They share NKG2A/CD94 with humans and the murine homolog of HLA-E is Qa1. The second inhibitory receptor family is Ly49, a family of C-type lectins that also recognize polymorphic class I molecules. All of these inhibitory receptors recognize MHCI and they thus enable the NK cells to monitor the function of the class I pathway. Viruses that interfere with the class I antigen-presenting pathway run the risk of rendering infected cells susceptible to NK lysis.

It is important to note that not all KIR and Ly49 molecules are inhibitory. Some lack cytoplasmic tails with immunoreceptor tyrosine-inhibition motifs (ITIM) and instead pair with adaptor molecules to activate cells. Furthermore, some NKG2 family members that recognize HLA-E molecules have an activating function. The function of the inhibitory members of these families in the control of NK lysis appears plausible; the function of the activating members is less clear (with the exception of Ly49H, discussed below).

VIRAL INTERFERENCE WITH NK RECOGNITION OF INFECTED CELLS

Several viruses have been described to interfere with the ability of NK cells to detect infection; this is summarized in Figure 4.

Human cytomegalovirus UL18 is a class I homolog – it shares 25 percent amino acid homology with classic class I, and pairs with host β_2-microglobulin for expression on the surface of infected cells. When it became appreciated that loss of cell surface class I, induced by HCMV infection, would make infected cells vulnerable to NK lysis, the idea that UL18 would engage NK inhibitory receptors and prevent NK lysis became an attractive hypothesis. Indeed Reyburn et al. (1997) used transfected cells expressing UL18 to demonstrate protection from NK lysis in vitro. However, it is controversial whether UL18 functions in this way in vivo. First, cell surface expression of UL18 in infected cells is very low. Second, none of the well-characterized NK inhibitory receptors have been shown to interact with UL18. Third, when a ligand for UL18 was identified (see section The leukocyte immunoglobulin-like receptors below), it was found to be mostly expressed on macrophages, B cells, and DCs, although it is also expressed on some NK cells (Cosman et al. 1997). The ligand, leukocyte immunoglobulin-like receptor 1 (LIR-1), is inhibitory, so it may indeed function to inhibit NK lysis.

Murine CMV also encodes a gene – *m144* – with homology to classic MHCI. The gene *m144* also pairs with β_2-microglobulin to produce a class I-like structure. Mice infected with a virus lacking *m144* control it better than they control wild-type virus (Farrell et al. 1997). The difference in titers is particularly evident 3 days after infection, when NK control is most important. Furthermore, mice depleted of NK cells show no difference in their ability to control wild-type virus or the *m144* deletion mutant. All this suggests that *m144* would inhibit NK recognition of infected cells. However, a direct demonstration that *m144* interacts with NK cells to inhibit their activation is lacking. Although it is clear that *m144* acts somewhere in the NK pathway, the exact site of action remains to be demonstrated. As with UL18, the discovery of other class I-interacting molecules (see The leukocyte immunoglobulin-like receptors below) raises possibilities other than direct interaction with NK inhibitory receptors.

Molluscum contagiosum virus is a poxvirus that establishes persistent infection, unlike other poxviruses. It also encodes an MHCI homolog of unknown function, which complexes with β_2-microglobulin (Senkevich and Moss 1998).

Another MCMV gene – *m152* – has been clearly shown to interfere with NK lysis. The gene *m152* is also loosely related to class I by secondary structure. Its best understood function is interference with antigen presentation to $CD8^+$ T cells (see below under Retention of class I molecules in pre-golgi compartments). However, Krmpotic et al. (2002) found a that a virus lacking *m152* had much lower titers 3 days after infection – a time at which NK cells are the main antiviral mechanism – than wild-type virus. This was surprising because *m152* is known to decrease cell surface expression of classical MHC1, and it was thought that it should therefore make the virus more (not less) vulnerable to

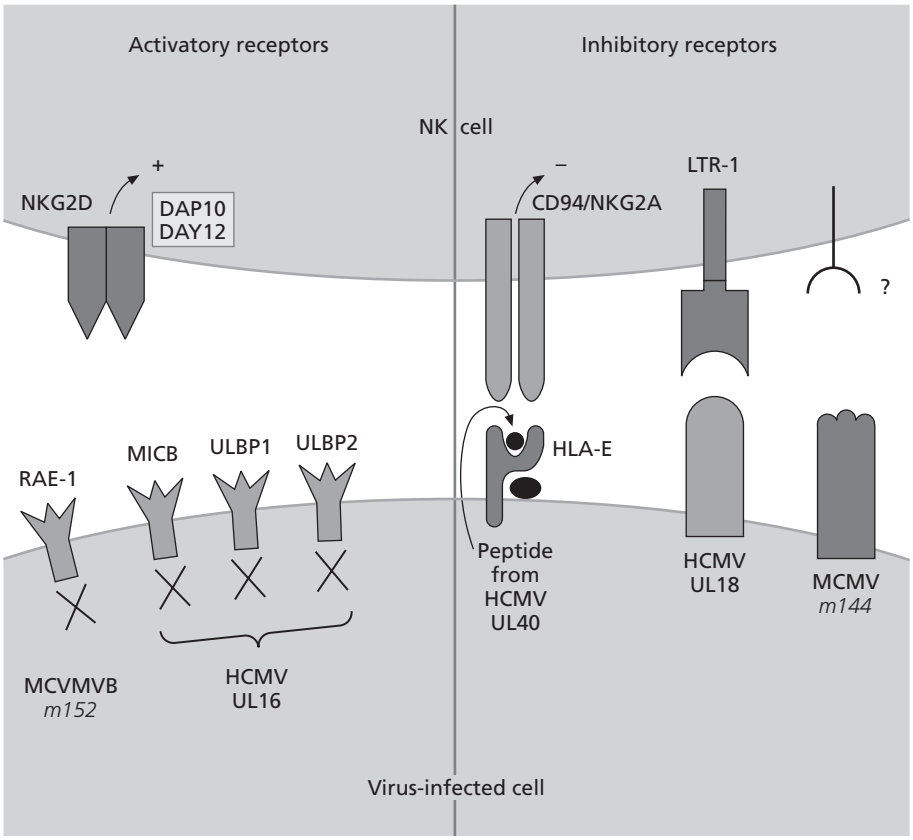

Figure 4 *Viral interference with natural killer (NK)-activating receptors and provision of 'decoys' for inhibitory receptors. See text for abbreviations.*

NK control. The riddle was solved when Krmpotic et al. found that *m152* also reduced the level of an NK ligand on the surface of infected cells. As described above, the RAEs and H60 are loosely class I-like molecules, and serve as a ligand for the important NK-activating receptor NKG2D. Cells infected with a virus lacking *m152* had high ligand levels and were more susceptible to NK lysis than those infected with wild-type virus.

In HCMV a soluble form of the *UL16* gene product was found to interact with human ligands for NKG2D: MICB, ULBP1, and ULBP2 (Cosman et al. 2001). The ULBPs were actually identified by their interaction with UL16. UL16 retains MICB, ULBP1, and ULBP2 inside the cell. In fact, HCMV increases the transcription of all NKG2D ligands, and cell surface expression of MICA and ULBP3, the two ligands not targeted by *UL16*, is increased by HCMV infection. How these contradictory effects translate into susceptibility to or protection from NK lysis is still an open question.

Another NK inhibitory effect has been described for HCMV. As described above, NKG2A/CD94 is an important inhibitory receptor on NK cells. NKG2A recognizes the nonpolymorphic HLA class I molecule HLA-E (Braud et al. 1998a). HLA-E binds peptides derived from the leader sequence of classical class I molecules, which must be transported back into the endoplasmic reticulum by transporter associated with antigen processing (TAP) (Braud et al. 1998b). HLA-E cell surface expression is reduced if classical class I is absent or if TAP is impaired. It thus serves to monitor the integrity of the class I pathway. As the HCMV genes *US2* and *US11* cause rapid destruction of newly synthesized class I (see below under Degradation of newly synthesized MHCI molecules) and *US6* blocks the function of TAP, HCMV infection should render cells vulnerable to NK lysis through silencing of NKG2A/CD94 signaling. However, another HCMV protein, UL40, has in its leader sequence a peptide capable of binding to HLA-E (Tomasec et al. 2000). Furthermore, this peptide remains in the endoplasmic reticulum after signal sequence cleavage and is able to bind to HLA-E in the absence of functional TAP. Thus HCMV is able to circumvent the HLA-E pathway. It is still controversial whether the relative effects of either UL40 or class I downregulation dominate the susceptibility of HCMV-infected cells to NK recognition, i.e. whether the final effect is susceptibility or protection (Falk et al. 2002; Wang et al. 2002a). Again, the final outcome may be different in different cell types, times after infection, etc.

HIV does not directly interfere with NK recognition. However, investigators have noted that HIV-nef interference with class I cell surface expression affects HLA-A and -B molecules but not HLA-C (Collins et al.

1998). As HLA-C isoforms are the most important ligands for KIRs, this may prevent HIV-infected cells becoming vulnerable to NK attack as a result of loss of KIR inhibition.

KSHV-K5 is known to downregulate cell surface classic class I molecules. However, it also downregulates intercellular adhesion molecule 1 (ICAM-1) and B7-1, known to be important for NK cell lysis (Ishido et al. 2000). In consequence, K5 expression protects transfected cells from NK lysis.

A viral gene has been reported which, instead of protecting from NK lysis, actually renders infected cells susceptible to a protective NK response. It was known that a gene in the NK locus has a major effect on the susceptibility of different mouse strains to MCMV. Mice from the resistant strains have a more effective NK cell response. It was recently discovered that the gene controlling resistance is *Ly49H* – an activating receptor found on a subset of NK cells. The surprising finding was that the ligand for *Ly49H* is not, as had been presumed, a host-encoded molecule upregulated by infection, but is actually a viral gene product encoded by the gene *m157* (Arase et al. 2002; Smith et al. 2002). The gene *m157* has no known other function and is dispensable for virus replication in vitro and in vivo. It also interacts with an inhibitory receptor, *Ly49C*, and investigators have postulated that this is its true evolutionary function.

THE LEUKOCYTE IMMUNOGLOBULIN-LIKE RECEPTORS

Human CMV encodes a molecule – UL18 – with 25 percent homology to MHCI heavy chain. As described above, it was assumed that UL18 would interact with KIRs and prevent NK lysis of HCMV-infected cells. This idea was supported when it was shown that cells transfected with UL18 were resistant to lysis by some NK cells (Reyburn et al. 1997). However, identification of the ligand for UL18 led to the discovery of an entirely new gene family – the leukocyte immunoglobulin-like receptors (LIR) (Cosman et al. 2001). The LIRs are structurally related to the KIRs and human IgA Fc-receptor, and are encoded in close proximity to those genes on chromosome 19. There are eight LIRs – all but one are membrane glycoproteins; some contain ITIMs, whereas others have an arginine in their transmembrane region which suggests that they pair with another chain and have an activating function (Fanger et al. 1999). The ligand identified for UL18 is LIR-1; its cytoplasmic tail contains ITIMs. It is expressed on most B cells and monocytes and a variable number of T cells and NK cells. In addition to UL18, LIR-1 binds to most HLA-A, -B, and -C molecules. The physiological function of this molecule, and hence what HCMV achieves by encoding a ligand for it, is currently unknown.

Most of the other LIRs are also expressed on monocyte and DCs but not on lymphocytes. LIR-2 also binds class I molecules, but the ligands for the other LIRs are not yet identified. The discovery of this family indicates that the role of MHCI in immunobiology is not yet fully understood, and this should be taken into account when considering the function of viral genes that inhibit class I expression.

EFFECTS ON THE ADAPTIVE IMMUNE RESPONSE

Viral interference with DC functions

The cellular arm of the adaptive immune response consists of CD4 and CD8 T cells. CD8 T cells are the most important effector arm of adaptive antiviral immunity. The effective antiviral T-cell response requires orchestration. Antigen-presenting cells (APC), usually DCs, capture antigen and travel from the site of infection to the draining lymph nodes, where they activate naïve T cells. Naïve T cells that recognize antigen on DCs remain trapped in the lymph node. They start to proliferate for several days, and acquire the effector phenotype. Activated effector T cells can enter tissues. This is essential for CD8 T cells to interact directly with and to lyse virus-infected cells. Infected tissues provide chemokine and cytokine signals that enable T cells to extravasate and direct them to the site of infection. In the tissues, CD8 T cells have two main effector mechanisms that are antiviral: cytolysis of infected cells and release of antiviral cytokines, especially IFN-γ. CD4 T cells can make antiviral cytokines, but also provide critical help for CD8 T cells and for antibody production. Viruses have found several points of intervention within this process. These will now be dealt with individually: first, processes that would affect both CD4 and CD8 T cells, followed by mechanisms specific for each cell type.

Among APCs, mainly DCs are able to activate naïve T cells. DCs are generated in the bone marrow, circulate in the blood, and enter tissues in an immature state. Immature DCs are active in phagocytosis, but are poor APCs as a result of intracellular retention of class I and class II molecules and low expression of costimulatory molecules such as CD80 and CD86. Immature DCs can phagocytose dying cells, cellular debris, immune complexes, and proteins. They can also be infected by many viruses. In the context of adequate mediators produced during infection, they differentiate to mature DCs that are extremely potent APCs and stimulators of T cells. Maturation also triggers their migration into the lymphatics and to the T-cell areas of draining lymph nodes. Maturation signals produced during virus infection include type I IFN from infected cells and TNF-α from tissue macrophages. DCs have two main ways of

activating CD8 T cells to initiate the T-cell response to viruses. First, infected DCs can present antigen through the classic endogenous pathway of MHCI-restricted antigen presentation. Second, they can 'crosspresent' antigens that they acquire by phagocytosis of proteins, which are degraded to peptides for loading on to their class I molecules. Sources of material that can be 'cross-presented' include cells dying by either apoptosis or necrosis; cellular debris, immune complexes, and perhaps heat shock proteins from dying cells that have bound viral peptides. Crosspresentation is described in Figure 5. The relative importance of the two DC presentation pathways depends on (1) the ability of viruses to directly infect DCs and (2) the extent to which viruses interfere with the direct presentation pathway (Figure 5).

For CD4 T cells, crosspresentation is the classical pathway of antigen presentation and is called exogenous presentation. Still controversial is the role of loading of class II molecules with endogenously synthesized viral proteins in infected class II-positive cells. This is discussed further below. Like CD8 T cells, naïve CD4 T cells are found only in blood and secondary lymphoid tissue, and they depend on trafficking of DCs to lymph nodes to be activated. Mature DCs that present viral antigen to naïve T cells are critical for the initiation of a T-cell response. There are three aspects of this with which viruses can interfere:

1 Interference with DC trafficking: DCs enter uninfected tissue, but they enter sites of infection in much greater numbers. Interference with chemokines and cytokines could affect migration.
2 Interference with the ability of DCs to present viral antigen: many viruses interfere with the class I antigen processing and presentation pathway. This would interfere with and perhaps prevent directly infected DCs from activating T cells, but would not interfere with crosspresentation. Although viruses might also be able to interfere with crosspresentation (perhaps via a secreted product), so far no such mechanism has been described.
3 Interference with the ability of immature DCs to mature, which is essential for APC function. The normal response of a DC to virus infection is to mature into an APC. Type I IFNs, induced by most virus infections, are powerful DC maturation stimuli. However, several viruses have been described that do not initiate maturation of DCs, and in fact interfere with the ability of the DCs to mature in response to other stimuli (Figure 6).

A well-studied viral interference with DC function occurs during measles virus infection; this infection elicits good protective immunity, including CD8 T cells, and yet is associated with a profound immunosuppression which supports additional infection by other infectious agents. This superinfection contributes to the morbidity and mortality associated with measles. The interaction of measles virus and DCs is complex. Measles virus infects DCs and induces their maturation and IL-12 production (Schnorr et al. 1997). This stimulates virus replication in the infected DCs. However, measles virus-infected DCs inhibit rather than promote proliferation of T cells. A few infected DCs are enough to inhibit the ability of a large number of uninfected

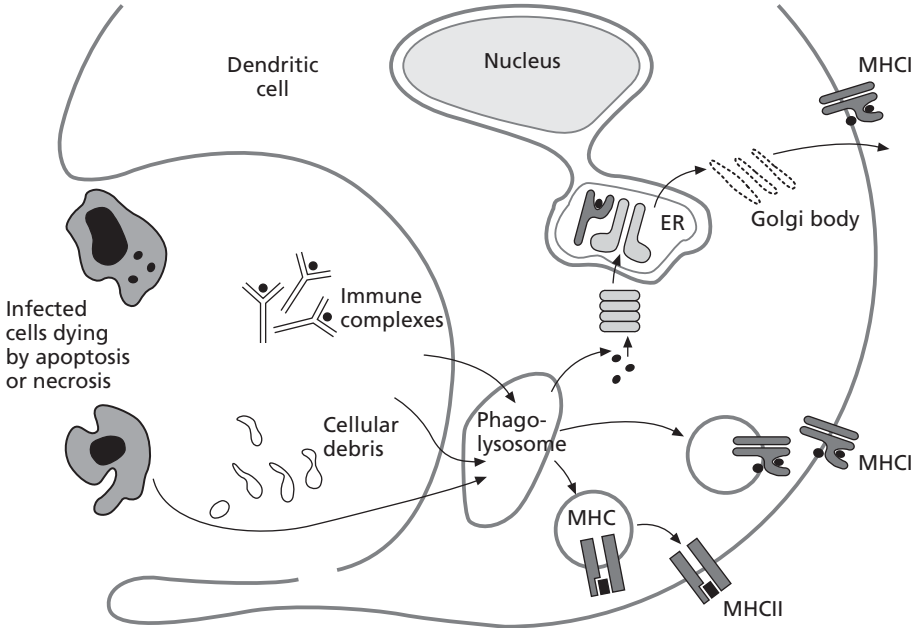

Figure 5 *Crosspresentation of viral antigens to CD8 T cells: activation of antiviral T cells despite immune evasion genes. Phagocytosomal material is re-presented on the dendritic cell's MHC molecules. The pathways for crosspresentation via MHCI are still poorly defined.*

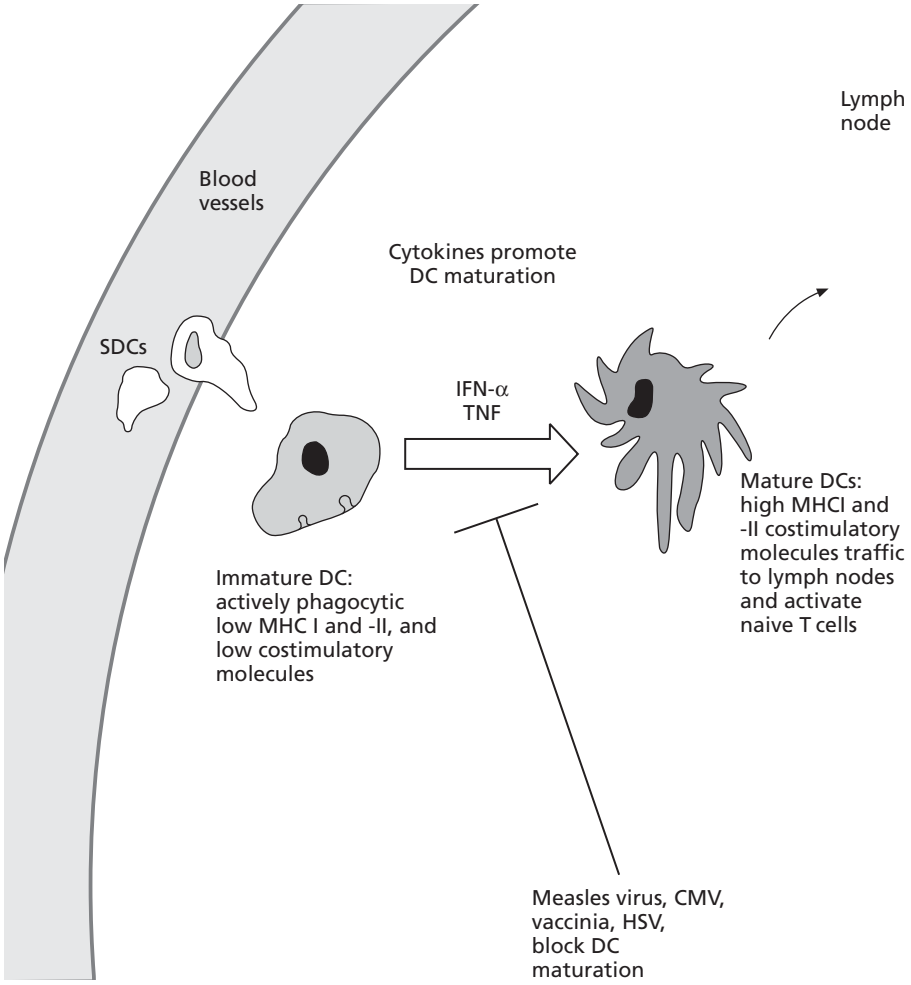

Figure 6 *Viral interference with dendritic cell (DC) maturation or function. CMV, cytomegalovirus; IFN-α, interferon α; TNF, tumor necrosis factor.*

DCs to promote T-cell proliferation (Grosjean et al. 1997; Schnorr et al. 1997). Measles virus induces the expression of the apoptosis-inducing ligand TRAIL on DCs (Vidalain et al. 2000); T cells and DCs cocultured with measles virus both undergo apoptosis (Fugier-Vivier et al. 1997; Servet-Delprat et al. 2000). Measles virus interference with DC function is thought to be the major mechanism of the generalized immunosuppression associated with MV infection.

Engelmayer et al. (1999) reported that VV impaired maturation of human DCs, and concluded that this would impair immunity. Drillien et al. (2000) also noted that VV inhibited maturation of human monocyte-derived DCs. However, VV-infected DCs efficiently stimulate memory T cells from infected individuals. In fact, infected DCs have been observed interacting with T cells in vivo (Norbury et al. 2002). Another study in mice concluded that both direct presentation by virus-infected DCs and crosspresentation contribute to CD8 T-cell priming in VV-infected mice (Basta et al. 2002). VV, the vaccine for smallpox, is the poster child of good viral immunogens. If VV does impair DC function, this effect is presumably mild and does not prevent an immune response.

Inhibition of DC maturation has also been reported for HSV (Salio et al. 1999) and MCMV (Andrews et al. 2001). The CD8 T-cell response to MCMV is thought to be largely achieved by crosspresentation (Gold et al. 2002), which suggests that functional DC impairment could play a role. HCMV is also thought to affect DC function. Moutaftsi et al. (2002) reported that HCMV impaired DC maturation. Mature DCs, on the other hand, were reported to increase costimulatory molecules after HCMV infection (Raftery et al. 2001). They also expressed the apoptosis-inducing ligands, FasL and TRAIL, suggesting that they might induce a generalized immunosuppression similar to measles.

Interference with antigen presentation in the MHC class I pathway

The most widely studied and best-appreciated viral immune evasion mechanisms have been found to affect

CD8 T-cell recognition of virus-infected cells. There are two basic strategies: viruses can interfere with the MHCI pathway of antigen presentation, or they can mutate the epitopes that CD8 T cells recognize, forcing the immune system to generate new effectors from naïve precursors.

Several viruses, mostly herpesviruses, have evolved genes that interfere with the MHCI pathway. Immune evasion genes of this type have been called viral genes that interfere with antigen presentation (VIPR) (Yewdell and Hill 2002). The pathway of MHCI-mediated antigen presentation is quite complex, and the past few years have seen a flurry of discoveries of viral gene products that interfere, to varying degrees of specificity, with almost every aspect of this pathway. Some viruses – notably CMV – actually encode several genes that all target this pathway. We begin this section by following the class I antigen presentation pathway and describing the various mechanisms that viruses use to attack it.

ANTIGEN DEGRADATION

The first step in antigen processing for the MHCI pathway is degradation of viral proteins in the cytosol, mostly by the proteasome. Proteasome function is vital for the health of the cells, and few viruses target this aspect. However, the EBNA-1 protein of EBV contains a long segment of repeated glycine and alanine residues, which renders the protein resistant to proteasomal degradation, and peptides for cytotoxic T lymphocyte (CTL) recognition are not generated (Levitskaya et al. 1995). EBNA-1 is the only protein that EBV needs to be expressed during latency, and this mechanism may help to prevent eradication of the latent virus pool.

When HCMV infects a cell the phosphoprotein pp65, a structural protein that has kinase activity, is also introduced. This protein is apparently able to prevent presentation of the immediate early (IE) peptide of the immunodominant IE1 protein, perhaps by phosphorylating IE1 and altering its proteolysis (Gilbert et al. 1996) (Figure 7).

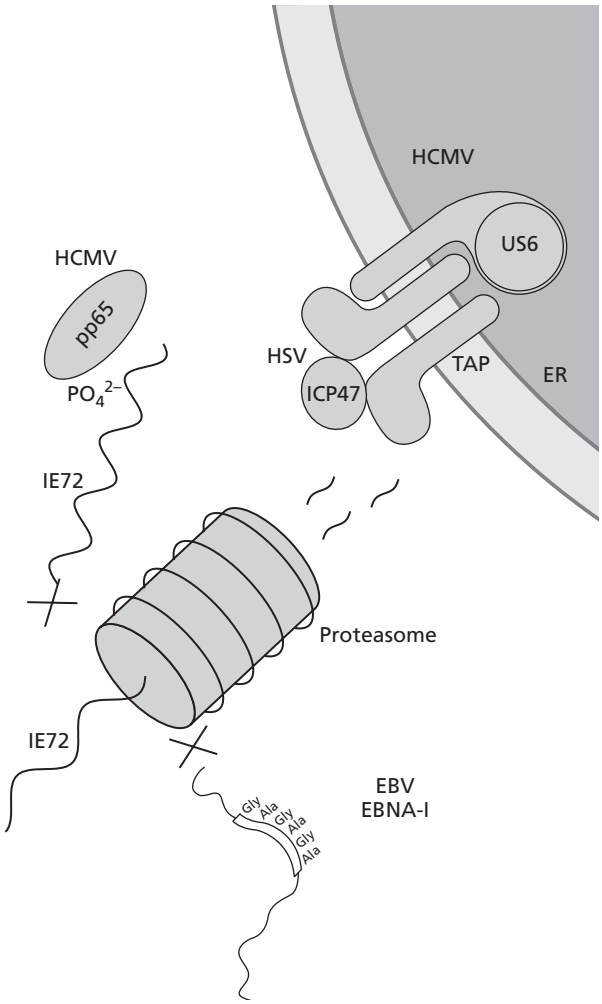

Figure 7 *Interference with production of peptides and transport into the endoplasmic reticulum (ER). See text for abbreviations.*

TRANSPORT OF PEPTIDES BY TAP

Peptides are transported by the TAP from the cytosol into the endoplasmic reticulum where they can bind to class I molecules. TAP is a member of the seven-transmembrane ATP-binding cassette family of transporters, and appears to have no other function. It can thus be incapacitated by viruses without impairing other cellular functions that the virus may need. TAP is specifically targeted by at least two VIPRs. The HSV IE gene *US12* encodes a polypeptide of 87 amino acids, ICP47, which is abundantly expressed in the cytosol (York et al. 1994). It binds to TAP and inhibits peptide transport, with the result that newly synthesized class I molecules are unable to leave the endoplasmic reticulum, and antigen presentation is prevented (Fruh et al. 1995; Hill et al. 1995). Both HSV-1 and HSV-2 encode ICP47; as a result of a frame shift mutation, they are homologous only in their first 35 amino acids, and this region of the molecule is all that is required for inhibition of TAP (Galocha et al. 1997).

The HCMV protein US6 also binds to TAP and inhibits peptide transport, although not as potently as ICP47 (Ahn et al. 1997; Hengel et al. 1997; Lehner et al. 1997). US6 is a transmembrane glycoprotein that binds TAP on the luminal side of the endoplasmic reticulum.

THE PEPTIDE-LOADING COMPLEX

In the endoplasmic reticulum, MHCI molecules associate with TAP as part of a peptide loading complex that also includes tapasin, calreticulin, and a thiol oxidoreductase. This complex not only ensures that class I is in the optimal place to acquire peptides, but also orchestrates peptide loading and provides poorly understood quality control functions. Several VIPRs associate with this complex, but it is not understood whether this is a coincidental consequence of binding their

main targets or whether it plays a role in their interference with the pathway. The adenovirus protein Ad5E3 19K binds TAP and interferes with the ability of tapasin to bring class I and TAP together in the peptide-loading complex (Bennett et al. 1999). This function may supplement its ability to retain class I (see below under Retention of class I molecules in pre-golgi compartments).

SYNTHESIS OF MHCI MOLECULES

Many viruses interfere with host gene expression, either globally or selectively. As newly synthesized class I molecules are required for peptide loading, interference with synthesis of MHCI affects antigen presentation. However, the extent to which this mechanism would affect the antiviral efficacy of CTL depends on a number of timing issues: the half-life of class I RNA (if transcription but not RNA stability is affected); the average residence time of MHCI in the endoplasmic reticulum (which varies considerably between class I isoforms); the timing in the viral replication cycle of antigen expression (the earliest expressed proteins and structural viral proteins that can be processed immediately upon viral entry are less affected); and the length of the viral replication cycle (viruses with long replication cycles can gain more from mechanisms that would only impact CTL recognition after a lag time of many hours or days). One virus for which interference with MHCI synthesis has a clear impact on CTL efficacy is HSV. The viral host protein shut off (vhs) factor encoded by HSV UL40 is a virion structural protein. Upon virus entry it strips RNAs from ribosomes, allowing viral transcripts to be translated at the expense of host transcripts. The function is especially potent in HSV-2: within half an hour of virus infection synthesis of host proteins, including MHCI, essentially ceases. HSV UL40 has been shown to affect CTL recognition of infected cells (Tigges et al. 1996).

DEGRADATION OF NEWLY SYNTHESIZED MHCI MOLECULES

One of the most effective VIPR mechanisms is that employed by the HCMV proteins US2 and US11. These proteins bind MHCI in the endoplasmic reticulum and cause it to be transported back through the translocon. In the cytosol, MHCI is ubiquitinylated and destroyed by the proteasome (Wiertz et al. 1996a,b). The process is very potent and in HCMV-infected fibroblasts metabolic labeling reveals very little class I (Beersma et al. 1993). These particular genes have been intensely studied, not just because of their immune evasion function, but also because they have helped to elucidate an important cell biological pathway – the degradation of endoplasmic reticulum proteins. US2 and US11 are both type I membrane glycoproteins, and both bind MHCI via their luminal domains. However, they are not structurally homologous, and show some differences in the way that they achieve MHCI destruction, e.g. the carboxyl end of US2, but not US11, is required for MHCI degradation (Furman et al. 2002). The cytoplasmic tail of MHCI is, however, required (Story et al. 1999). These molecules show a specificity for class I isoforms and degrade HLA-A and -B, but not HLA-C, molecules (Schust et al. 1998). HLA-C can present peptide antigens to CTL, but it also has an important role as ligand for inhibitory KIR receptors on NK cells (see above).

The mouse γ2 herpesvirus 68 also causes destruction of class I molecules. The K3 protein of MHV-68 is a ubiquitin ligase: it ubiquitinylates the cytoplasmic tail of endoplasmic reticulum-resident MHCI, targeting it for destruction in the cytosol (Boname and Stevenson 2001). Interestingly, the highly homologous K3 and K5 proteins of KSHV also ubiquitinylate MHCI, but this serves to target cell surface MHCI for degradation (Figure 8).

RETENTION OF CLASS I MOLECULES IN PRE-GOLGI COMPARTMENTS

Several VIPRs prevent MHCI from trafficking to the cell surface without causing their destruction. The adenovirus 5 protein E3 19K contains a di-lysine motif in its cytoplasmic tail; this motif binds to coat protein 1 (COP-1), which retrieves vesicles from the Golgi and returns them to the endoplasmic reticulum (Jefferies and Burgert 1990). In fact, this pathway was identified because of the E3 19K protein. The result is that MHC I is retained in the endoplasmic reticulum. Ad5E3 19K does not interact with all MHCI molecules equally, and the result is that some MHCI isoforms are more efficiently retained than others.

The HCMV protein US3 also causes MHCI to be retained in the endoplasmic reticulum. US3 binds to peptide-loaded MHCI molecules. The mechanism of retention is not clear, because US3 does not contain an endoplasmic reticulum retention motif, and is in fact exported (Ahn et al. 1996; Jones et al. 1996). It is thought that the mechanism of retention involves repeated release and rebinding by newly synthesized US3 (Gruhler et al. 2000). As with most of the HCMV VIPRs, US3 has been studied primarily in transfected cells. In infected cells, the destruction of newly synthesized MHCI as a result of US2 and US11 is so rapid that the role of US3 is hard to appreciate. US3 is synthesized earlier in the viral replication cycle than US2 and US11, and it has been hypothesized that it prepares MHCI for destruction by US2 and US11 (Ahn et al. 1996).

Murine CMV also encodes a VIPR that retains class I molecules. The *m152/gp40* causes MHCI to be retained in the endoplasmic reticulum–Golgi intermediate compartment (ERGIC) and, as with US3, the mechanism is unclear (Ziegler et al. 1997). It has quite different efficacy against different MHCI isoforms (Kavanagh et al. 2001). Yet even for isoforms in which retention is not especially impressive (e.g. Kb, which is only 50 percent retained by *m152*), *m152* has a profound

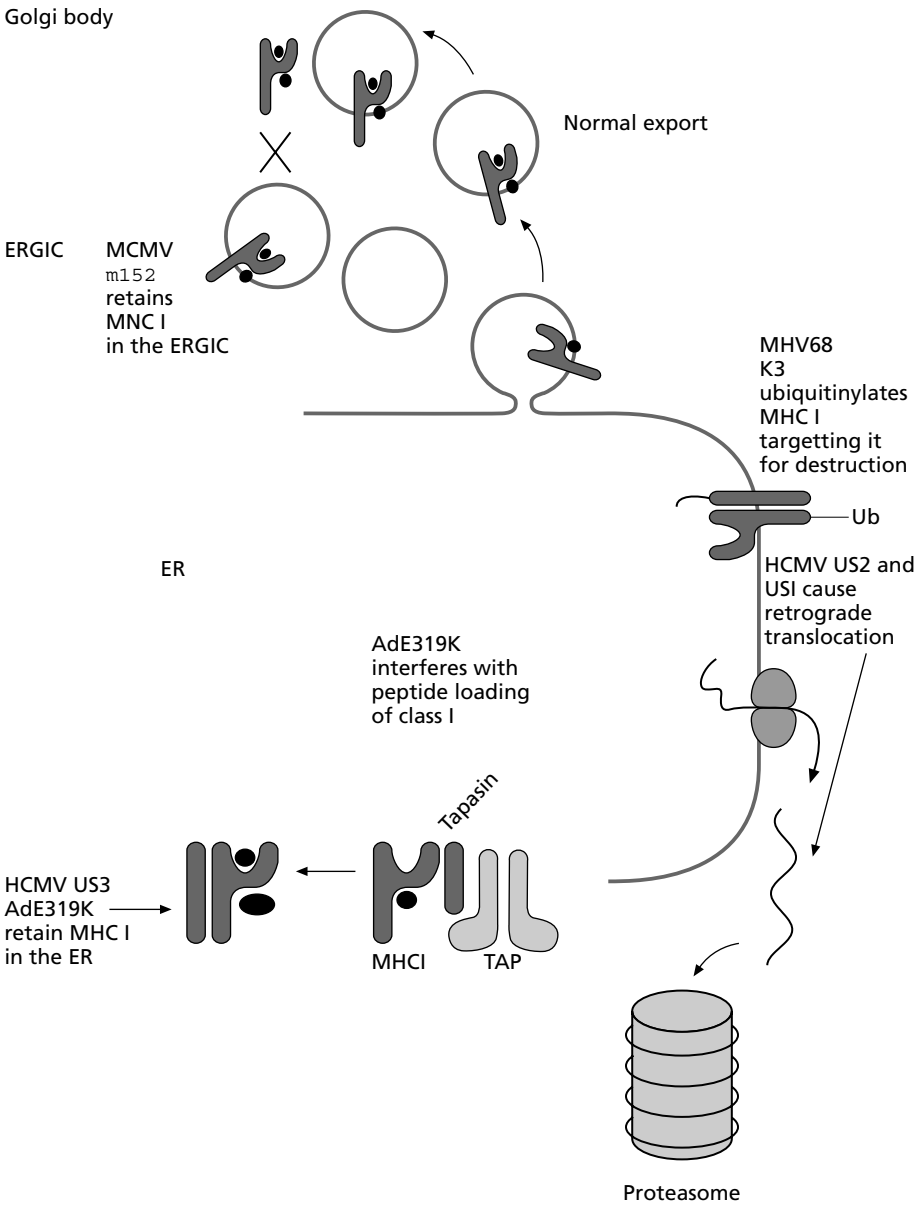

Figure 8 *Interference with MHC class I in the endoplasmic reticulum (ER) and endoplasmic reticulum Golgi intermediate compartment (ERGIC).*

effect on antigen presentation. Cells infected with wild-type virus are not detected by CTL, but cells infected with a virus lacking *m152* are readily detected. To prevent recognition of wild-type-infected cells by Kb-restricted CTL, the virus needs the two other MCMV VIPRs – *m4* and *m6* – the mechanisms of which are discussed below. Even so, the importance of *m152* remains enigmatic, and it may indicate that there is more profound synergism in the functions of these genes than is appreciated. Something similar may explain why HCMV needs its four VIPRs. As discussed above, in addition to retaining classical MHCI molecules, *m152* also prevents surface expression of molecules, which activates NK cells (Krmpotic et al. 2002).

REMOVAL OF MHCI MOLECULES FROM THE GOLGI APPARATUS OR THE CELL SURFACE

Several VIPRs remove class I from the cell surface. The KSHV genes *K3* and *K5* both reduce cell-surface MHCI expression. K3 ubiquitinylates MHCI after endoplasmic reticulum export. This signals MHCI internalization from the plasma membrane for endosomal degradation (Hewitt et al. 2002). The MCMV protein m6 contains a di-leucine motif in its cytoplasmic tail, which sorts it to lysosomes. It binds MHCI in the endoplasmic reticulum, and targets MHCI to the lysosome for destruction (Reusch et al. 1999). Of the three MCMV VIPRs, m6 has by far the most profound effect on cell-surface class I; from about 6 h after infection MHCI is rapidly lost

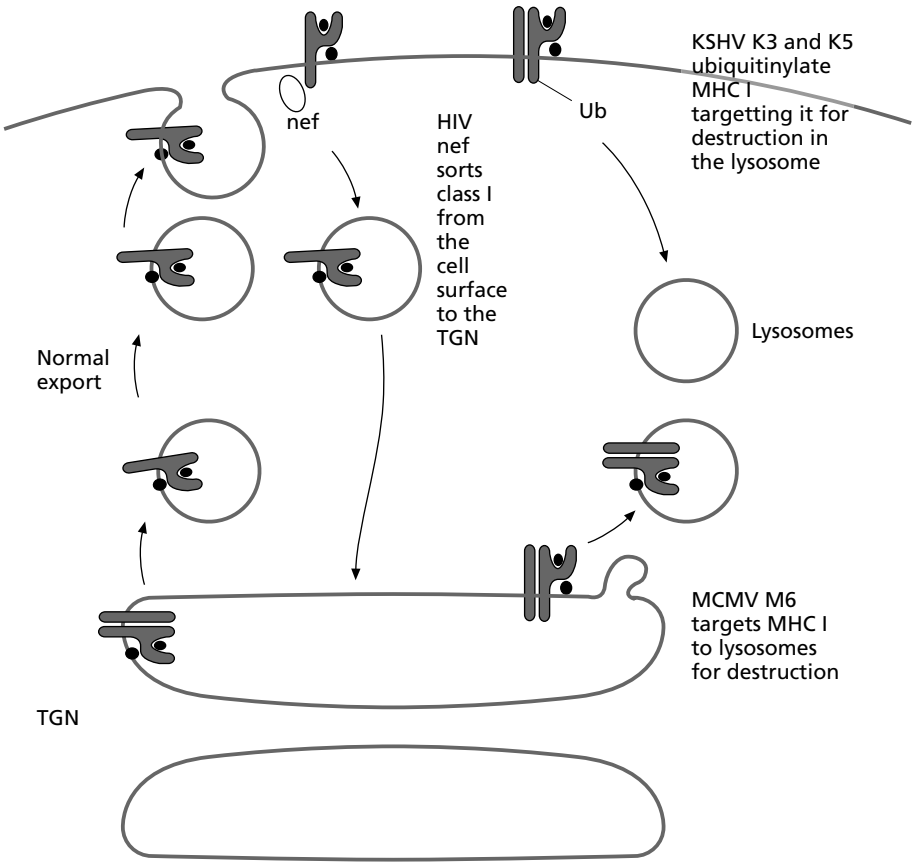

Figure 9 *Interference with MHC class I at the Golgi body and cell surface.*

from the cell surface if m6 is present (Wagner et al. 2002).

The HIV (and simian immunodeficiency virus (SIV)) nef protein serves a number of functions. One of them is to remove MHCI from the cell surface and take it to the trans Golgi network (TGN) – an effect that has been shown to impair CTL destruction of HIV-infected cells. The mechanism of action of HIV nef is quite different from that of KSHV-K3. Nef binds to the PACS-1 protein that sorts molecules to the TGN: presumably it acts as a bridge between class I and PACS-1 (Piguet et al. 2000) (Figure 9).

The MCMV protein m4/gp34 binds to MHCI both in the endoplasmic reticulum and at the cell surface. m4 is necessary to prevent lysis of infected cells by K^b-restricted CTLs (Kavanagh et al. 2001). The mechanism of action of m4 is not understood, but it is likely that its association with class I at the cell surface prevents the productive engagement of the TCR.

CD8 T-cell epitope variation

With the exception of nef, all the VIPRs described above are encoded by large DNA viruses, the coding capacity of which gives them the luxury of such highly specialized immune evasion devices. Small RNA viruses have also other means of avoiding CTLs. As a result of their rapid mutation rate, they exist in nature as a diverse genetic mix, often referred to as a 'viral swarm'. Mutations in CTL epitopes should allow the selection of escape variants, unless the exact epitope sequence is crucial for viral replicative function. This means that, as CTL clones develop and become immunodominant, virus variants arise that escape detection. Whether CTL escape mutants help the virus to persist in a host has been a matter of debate for some time. However, recent evidence in both monkeys and humans demonstrates that mutants of a particular epitope have a selective advantage in hosts that possess the MHCI molecule capable of binding the epitope, but not in hosts that do not possess that allele (Allen et al. 2000; Goulder et al. 2001).

Significance of viral interference with CD8 function in vivo

Most of the mechanisms reported above have been identified in vitro, and many of them have been described only using cells transfected with an isolated viral gene driven by a strong promoter. Their significance for infected cell recognition by CD8 T cells in vivo remains to be demonstrated. Obviously, true in vivo studies can be carried out only in animal models. The mouse is by far the most useful model for this purpose, although the importance of the HIV epidemic has led to studies of

SIV in infected macaques. As a result of the high degree of variation between the MHCs of different species, and the specificity of VIPRs for MHCI isofoms, studies of immune evasion need to be conducted in the natural virus host. For mice, MCMV is the most useful model, although the vole virus MHV-68 infects laboratory mice well and has provided important insights.

The first VIPR to be studied in vivo was the MCMV gene *m152*. Although wild-type MCMV-infected cells often escape detection by CTLs in vitro, cells infected with viruses lacking *m152* are always readily detected by CTLs. Krmpotic et al. showed that a virus lacking *m152* grew to about a log lower titer at day 7 (the time of peak CTL activity) than wild-type virus, but grew to the same titers in CD8 T-cell-deficient animals (Krmpotic et al. 1999). This effect was modest given the impact that *m152* has on CTL recognition in vitro, and challenges our concept of CD8 T-cell effector function in vivo. It has further been noted that a viral epitope whose presentation is completely abolished by *m152* in vitro is nevertheless equally immunodominant in mice infected with wild-type virus and with virus lacking *m152*, at least during the acute response. This suggests that cross-presentation is the main mode of antigen presentation driving the acute CTL response (Gold et al. 2002). However, viruses lacking *m152*, or indeed all three VIPRs, continue to provoke a very strong CTL response throughout the life of the animal. Therefore, it is unclear how the VIPRs of MCMV modulate the immunobiology of the virus.

MHV-68 K3 downregulates MHCI and prevents CTL recognition of infected cells. MHV-68 has a complex pattern of infection, analogous to EBV (Doherty et al. 2001). After initial replication in the lungs, which is controlled by IFNs and to some extent by CD4 T cells and CD8 T cells, MHV-68 seeds the splenic B cells. These undergo a massive CD4-dependent proliferation, with concomitant amplification of the latent virus load. This situation is brought under control by the immune response, and a truly latent infection is established. Although expression of viral genes is limited during the splenic amplification phase, K3 is expressed. A virus lacking K3 grew to normal titers in the initial lung infection, but did not undergo splenic amplification unless CD8 T cells were removed (Stevenson et al. 2002). Thus this VIPR function is thought to be to prevent CD8 T-cell control of the splenic amplification stage.

The selective advantage of CTL escape mutants in SIV and HIV infection in vivo has been clearly established, as described above under CD8 T-cell epitope variation. There is also evidence that the MHCI downregulating ability of nef is important. As nef has multiple functions, a specific mutant that affected its ability to downregulate MHCI, but not CD4, molecules was made. The mutant and wild-type viruses grew equally well in vitro. However, because the mutation affected a single codon, a mutation back to the wild-type sequence occurred in all four animals infected with the mutant virus within a few weeks (Munch et al. 2001). This suggested a strong selective pressure for the ability to downregulate MHCI.

Modulation of MHCII expression

CD4 T cells play a role in antiviral immunity, but the exact role is controversial. They provide essential help for B cells, and effective CD8 memory also depends on CD4 T cells. Two mechanisms may be involved in CD4 T-cell help for CD8 T cells: secretion of growth-supporting cytokines such as IL-2 and activation of DCs for activation of CD8 T cells. This so-called 'licensing' role requires direct recognition of the DCs by the CD4 T cell. CD4 T cells may also be direct antiviral effectors in their own right. They synthesize antiviral cytokines, especially IFN-γ, and if stimulated by professional APCs in the vicinity of the infection their role in secreting IFN-γ may be significant. Also, some viruses replicate in professional APCs that express MHCII, and many somatic cells are induced to express MHCII by IFN-γ. If these cells express class II loaded with viral antigen, CD4 T cells may have a direct antiviral effect by either killing the infected cell or secretion of cytokines.

Several viruses decrease the cell surface expression of class II by interfering with its synthesis. Most non-hemopoietic cells do not express MHCII, but (at least in humans) can be induced to do so by IFN-γ. Viruses such as herpesviruses and adenoviruses that interfere with IFN-γ signaling pathways will therefore interfere with induction of class II on these cells. MCMV induces the secretion of IL-10 by macrophages, and this leads to a decrease in macrophage MHCII expression (Redpath et al. 1999). Cells infected with HCMV also have decreased cell surface MHCII as a result of transcriptional inhibition of MHCII (Sedmak et al. 1994).

Some of the same HCMV proteins that interfere with MHCI expression have also been shown – in transfected cells – to interfere with MHCII in a similar manner. US2 causes HLA-DRα chains to be re-transported into the cytosol and degraded by the proteasome. Interestingly, it has the same effect on the α chain of HLA-DM, the essential chaperone for peptide loading on to class II (Tomazin et al. 1999). US3 has also been shown to cause intracellular MHCII retention. (Hegde et al. 2002). From the above, it is clear that there may be some advantages to viruses in interfering with MHCII molecules, but in general the functional evidence for interference with presentation of endogenous viral antigens is lacking, and there are no in vivo data. The real significance of these phenomena remains to be demonstrated.

Superantigens

Some viruses manipulate the immune system by stimulating T cells of irrelevant specificity. The B-type

retrovirus, mouse mammary tumor virus (MMTV), encodes a superantigen that binds to certain TCR β chains and to MHCII, causing a massive proliferation of all CD4 T cells with the appropriate TCR. These activated T cells provide the necessary stimulation to drive proliferation of virus-infected B cells, which is essential for the infective process (Huber et al. 1994). EBV also has superantigen-like activity. Proliferation of CD4 T cells expressing the V-β13 TCR chain is a feature of EBV infection (Sutkowski et al. 1996). It has recently been shown that EBV activates an endogenous human retrovirus, HERV-K18, the envelope glycoprotein of which has superantigen activity (Sutkowski et al. 2001). Whether this activity plays a role in EBV pathogenesis is unclear but, as EBV undergoes latency in B cells, concomitant B-cell proliferation could aid the establishment of a latent virus pool.

Inhibition of humoral immunity

The production of antibodies specific to viral antigens may neutralize virus particles and thus prevent the infection of susceptible cells. Antibodies bound to viral antigens of cells can be detected by Fc-receptor-carrying effector cells. Viral antigens can activate the complement cascade, directly or in association with antibodies, leading to the destruction of infected cells or enveloped virus particles. Viruses with an RNA genome accumulate mutations caused by the low fidelity of the RNA polymerase. Virus particles with different antigenic properties may evade recognition by specific antibodies. Genetic variability may also generate variant peptide sequences representing new antigens or losing the ability to bind to MHC molecules, thus evading recognition by the cellular immune system as well.

Herpes simples virus and other viruses encode receptors for the Fc domain of IgG to evade the action of antibodies (Johnson and Hill 1998) (Figure 10).

In the case of HSV, glycoproteins gE and gI form a heterodimeric Fc receptor that participates in a process termed 'bipolar bridging', in which antibodies bind to their specific HSV antigen and simultaneously interact with gE–gI (Lehner et al. 1975; Frank and Friedman 1989). In this way, the viral Fc receptors inhibit complement-mediated antibody neutralization and antibody-dependent cellular cytotoxicity by cells carrying Fc receptors. HSV gE–gI may also bind other ligands and it has been suggested that it acts as a receptor-binding glycoprotein in the process of cell-to-cell spread.

Several members of the herpesvirus family encode homologs of complement regulatory proteins that block the complement cascade in several ways (Johnson and Hill 1998; Favoreel et al. 2003).

The HSV glycoprotein gC binds the complement factor C3; it protects cell-free virus from complement-mediated neutralization and inhibits the lysis of HSV-infected cells by antibody and complement (Lubinski et al. 1999). HSV gC also functions in virus attachment to cell-surface glycosaminoglycans, especially on the basolateral surfaces of epithelial cells (Sears et al. 1991); thus it has been difficult to interpret the attenuated phenotype of gC virus mutants in vivo (Lubinski et al. 1999). However, in C3 knock-out mice, the disease caused by the gC virus mutant was similar to that of wild-type HSV, suggesting a major role of gC in resistance to complement (Lubinski et al. 1999). HVS, a virus that infects monkeys, encodes a homolog of the

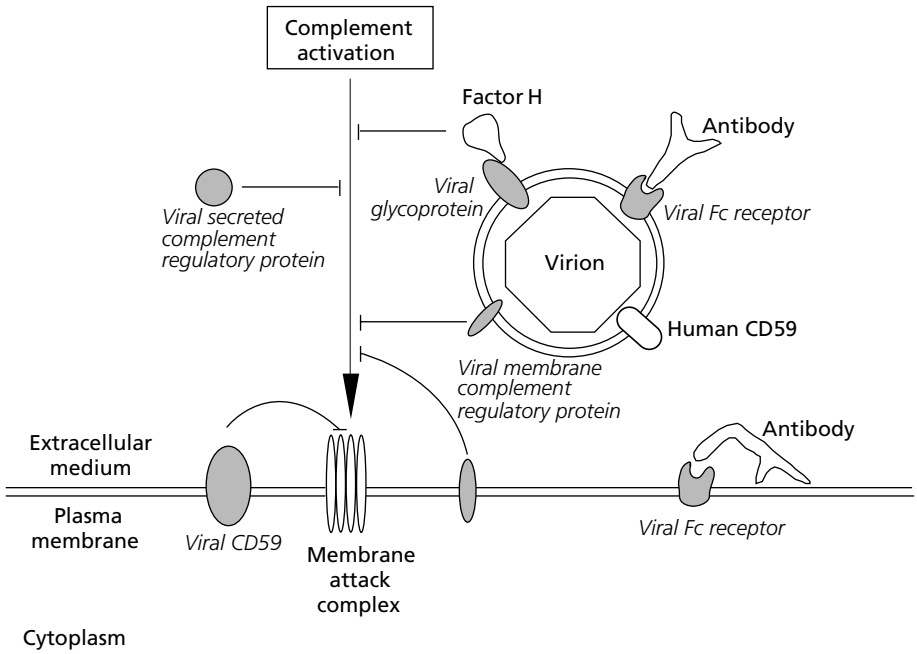

Figure 10 *Viral modulation of complement and antibody responses.*

inhibitor of the membrane attack complex CD59, which protects the infected cells from complement-mediated lysis (Rother et al. 1994).

A strategy used by HIV is to recruit the soluble factor H that inhibits complement activation by interacting with the gp120–gp41 complex (Stoiber et al. 1996). Removal of factor H from human serum augments the effect of complement on HIV-infected cells. The poxviruses variola virus (VaV), VV, and CPV encode a secreted protein, known as viral complement control protein (VCP), which blocks the classic and alternate pathways of complement activation (Kotwal et al. 1990; Rosengard et al. 2002). Inactivation of the VCP gene in VV causes virus attenuation in animal models, demonstrating an important role of this protein in preventing host defense mechanisms and a role for complement in antiviral immunity (Isaacs et al. 1992). Interestingly, inactivation of VCP from CPV caused a substantial increase in the inflammatory response in infected mice compared with wild-type CPV infections (Miller et al. 1997). This illustrated that inhibition of the inflammatory response by viral proteins may reduce tissue damage and allow virus replication in host cells that would otherwise be eliminated by the immune response.

Instead of encoding viral homologs of host proteins, HIV, VV, and HCMV, incorporate into the virion envelope complement regulatory proteins, such as CD56 and CD59, which confer complement resistance to the virus particle (Spear et al. 1995; Vanderplasschen et al. 1998)

CONCLUSIONS

A simplistic view of a virus–host interaction is that of a fierce competition between the virus infecting and replicating in a cell until its death, and then spreading to uninfected cells and tissues, whereas the immune system of the host seeks to eliminate all infected cells. This may be true for viruses that are restricted in their growth to mucosal surfaces, those that replicate fast, and those that are directly transmitted. Many viruses replicate slowly and have a tropism only for specific tissues in certain organs to which they have to be transported or disseminated, and often the sites of entry and the sites of release differ. Cell tropism is defined not only by the virus' inability to infect other tissues, but also as a result of the stringent immune control of the host which limits viral spread. Under conditions of immune suppression herpesviruses can infect many tissues, showing that the restriction of the infection to certain sites reflects the virus–host balance of the immunocompetent host. Therefore, the diversity in the biology of closely related viruses has been shaped by evolution, and the biological diversity reflects the function of viral proteins that have been selected to modulate cellular functions.

To describe viral functions as immunoevasive may have been correct for those that directly interfered with antigen processing in the MHCI and MHCII pathways. The reader is cautioned to treat the growing list of viral immune evasion strategies with some skepticism. These strategies are best regarded as modifiers of the immune response, not as immune evasion, e.g. despite the mechanisms described for herpesviruses, they are highly susceptible to NK control in vivo. In fact, recurrent herpesvirus infection is the clinical hallmark of NK deficiency. Later, a host of viral effects on cell functions were also listed as immunoevasive. However, many of these functions affect not only cells of the immune system, e.g. viral functions that affect apoptosis may serve to inhibit proapoptotic molecules released from NK and T cells. However, in the absence of viral anti-apoptotic functions some herpesviruses completely fail to replicate in a number of cell types. Other herpesviruses use functions to keep their host cells in a state of continuous division and to prevent cell death at the same time. Thus, these functions select the viral host cell range and define the biology of a virus.

In a similar vein, the research on viral modulation of chemokine networks has led to hypotheses on Janus-like effects of these viral proteins. A nonfunctional receptor can neutralize the cell-attractive function of a chemokine for cells of the immune system, and thus truly serve an immunoevasive function. On the other hand, there are virus-encoded chemokines that attract host cells. It is thought that these cells serve the virus for reaching target tissues. A remarkable aspect is that some of the cells that provide the 'taxi' service are those that normally would fight the viral infection. Therefore, there is certainly a score that orchestrates the roles of viral chemokines and chemokine receptors in viral dissemination and persistence, but it will take years to understand the music.

Examples of viral proteins that modulate host immune functions presented in this section were mainly taken from viruses with large DNA genomes. In part this is the result of the limited expertise of the authors. Second, many of these functions were first detected in DNA viruses. There is no doubt that several RNA viruses that were not been listed also encode such functions. In general, it appears that viruses need functions to dampen the function of innate immunity and the powerful antiviral functions of the soluble mediators such as the interferons. The analysis of viral functions that affect soluble mediators and/or their subsequent signaling cascades is an area of active research. Another reason for reporting on DNA virus functions is the working hypothesis that in a large virus genome a protein would perhaps serve only one function. There is the tacit belief that the function seen for the isolated gene in vitro also represents the functions that it has in the viral context in vivo. This may probably turn out to be not entirely correct and examples have been mentioned where one protein affects different antiviral principles. If this is true, the pressure for multi-

functionality of proteins is even higher in RNA viruses with their smaller genomes.

In apparent contrast to the multifunctionality of proteins is the fact that some viruses encode multiple genes for similar functions, all of which attack the class I pathway. It is not always clear what the purpose of this multiplicity is. One purpose appears to be to deal with MHC polymorphism. MHCI molecules belong to the most polymorphic proteins, as a result of the three class loci – HLA-A, -B, and -C in humans – and to extensive polymorphism at each locus. The length of coevolution of class I and viruses – particularly herpesviruses – makes it likely that some of this polymorphism has evolved to counteract VIPRs. In fact, many VIPRs deal with different class I isoforms with different degrees of efficiency. Thus, the function of some viral proteins are considered complementary. Another function for multiple genes is cooperativity: neither gene is capable of inhibiting antigen presentation alone, but together they function effectively to prevent CTLs recognizing infected cells. A similar multiplicity of genes with related function is also seen with respect to genes controlling apoptosis, and genes controlling chemokine and cytokine networks.

The analysis of the principles evolved by the viruses to target the same mechanism, e.g. the peptide transport or MHCI maturation, indicates that the biological problem – defense against CD8 T-cell control – has been independently addressed by the α and β herpesviruses. Analogous but mechanistically completely different solutions were found. This indicates that the virus subfamilies were already separated before the acquisition of these functions. The primordial immune system fighting the archetype herpesvirus progenitor lacking this function was different as well. There is a strong belief that the constant attack by viruses has shaped both the virus and the mammalian immune system that we know today. Some viral immunomodulatory functions, e.g. some antiapoptotic genes, operate across species barriers, whereas others, e.g. MHCI modulators, often do not. This is explained by the coevolution of viruses with their hosts and could mean that the host-specific functions were acquired at a later stage.

The true function of the immunomodulatory genes can be delineated only by in vivo studies using appropriate combinations of virus mutants and host mutants. Given the plethora of genes, the redundancy of related functions, the multifunctionality and cooperativity of proteins, and the intricate interplay of functions that act differently on different cells at different states of activation and differentiation, and with a different efficacy with respect to the genetic background of the host, it is clear that it will take a long time to test present concepts and to develop a conceptual network of hierarchical functions. This may be of use for modern medicine with its new concepts of treatment that affect immune functions and thus disturb the virus–host balance so carefully tuned by evolution.

INTRODUCTION

The success of pathogenic microorganisms is dependent on their survival and replication in the face of antimicrobial defense mechanisms, mediated by innate and adaptive responses of the host's immune system. Although the immune system is capable of preventing infection, and eliminating or containing most bacteria, many, if not all, bacterial pathogens have evolved strategies to evade or suppress immune responses to prolong their survival in the host. Ideally, the bacteria should be capable of avoiding or modulating innate and adaptive immunity to such an extent that the host does not succumb to a lethal infection but survives to pass on the organisms to secondary hosts.

Innate immunity

Following infection of host tissue with pathogenic bacteria, tissue macrophages quickly phagocytose and attempt to kill the bacteria (Figure 1). This initiates an inflammatory response with the release of cytokines and chemokines and the recruitment of neutrophils, monocytes, and lymphocytes to the site of infection. Binding of conserved secreted or cell-surface bacterial products to molecular structures, called pathogen recognition receptors (PRR), on cells of the innate immune system activates immune response genes, leading to inflammatory cytokine and chemokine production, and enhanced cell surface expression of molecules involved in antigen presentation (Janeway and Medzhitov 2002).

Activation of the alternate complement pathway by bacterial cell wall components results in the production of C3b, which opsonizes bacteria and, together with antibodies, facilitates their phagocytosis by neutrophils and macrophages. Bacteria also activate the classic pathway of complement. The complement membrane attack complex can directly kill certain bacteria and participate in the inflammatory response.

Once inside the phagocytic cells, the bacteria-containing phagosome undergoes a series of fusions with endosomes and lysosomes to form a phagolysosome in which the bacteria are killed by a variety of mechanisms, including reactive oxygen- and nitrogen-dependent mechanisms. However, phagocytic and killing mechanisms of host cells can be overcome by various physical and biochemical evasion strategies evolved by the bacteria. The composition of the bacterial cell wall has a major influence on the ability of phagocytic cells to take up and destroy the bacteria. All bacteria have an inner cell membrane and peptidoglycan layer, which can be attacked by lysozymes and enzymes in the lysosomal vesicles of phagocytic cells. Gram-negative bacteria have an outer lipid bilayer (with lipopolysaccharide), which can be attacked by cationic lipids and complement. Certain bacteria have capsules that prevent phagocytosis or have an extremely complex cell wall (e.g. mycobacteria), which is highly resistant to killing. Bacteria

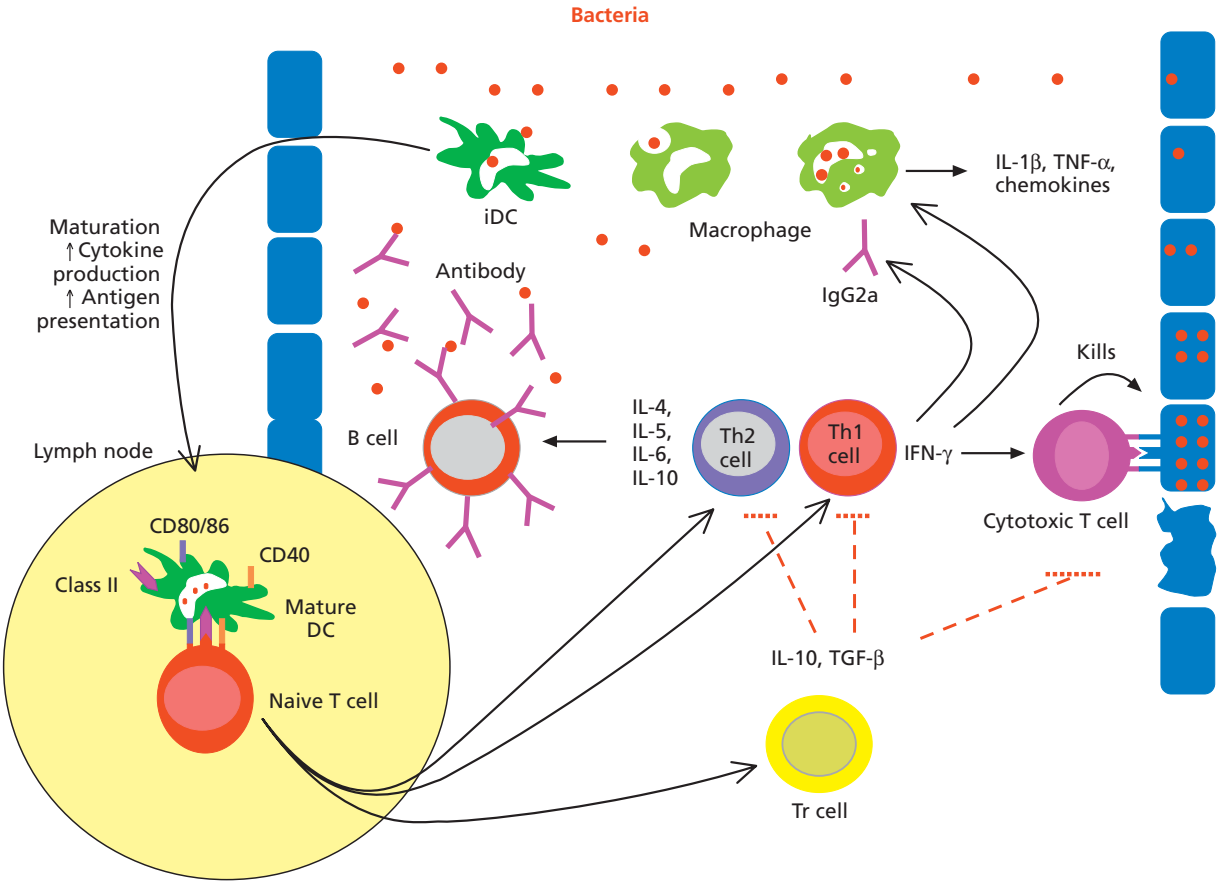

Figure 1 *Innate and adaptive immunity to bacteria. Bacteria that enter mucosal tissue, such as the lungs or gastrointestinal tract, are phagocytosed by macrophages and dendritic cells (DCs) of the innate immune system. Immature DCs (iDC) are activated and migrate to the draining lymph node, where they present processed bacterial antigens to naïve T cells. Effector T cells migrate back to the tissues and mediate and regulate the adaptive immune response to the bacteria. T-helper (Th1) cells secrete interferon γ (IFN-γ), which activates macrophages to kill the intracellular bacteria and cytotoxic T lymphocytes (CTL) to kill host cells infected with intracellular bacteria. Th2 and Th1 cells secrete cytokines that activate B-cell antibody production, which prevents bacteria binding to host cells, promotes opsonization, or neutralizes toxins. Finally, Tr cells turn off the adaptive immune response and limit collateral damage to host tissues.*

can also inhibit killing by preventing phagosome–lysosome fusion or by inducing lysosomal discharge into the cytoplasm. Induction of apoptosis in neutrophils, macrophages, and dendritic cells (DC), critical cells in antibacterial host defense and in activating adaptive immunity, is the ultimate subversion strategy evolved by a number of bacterial species to protective immune responses of the host.

Adaptive immunity

Adaptive immune responses are mediated by lymphocytes, called T and B cells. B cells produce antibodies, whereas $CD8^+$ T cells kill host cells infected with intracellular microorganisms and $CD4^+$ T cells provide help for B-cell production of antibody and regulate the immune response to infection (see Figure 1). In addition to $CD4^+$ and $CD8^+$ T cells, unconventional T cells, including γδ T cells which recognize phospholigands and CD1-restricted αβ T cells or T cells that express natural killer (NK) markers, termed NKT cells, which recognize glycolipids, also play a role in immunity to intracellular bacteria (Schaible and Kaufmann 2000). Although it takes days rather than hours before the adaptive immune response is effective, unlike the innate immune system, it is able to recall previous encounters with antigen, through the activation of memory T and B cells. Therefore a second or subsequent infection with the bacteria is dealt with more effectively.

After uptake of the bacteria by a macrophage or DC, the professional antigen-presenting cells (APC), process and present peptides of the bacterial antigens to T cells in association with major histocompatibility complex (MHC) molecules on their cell surface. All bacteria, whether they survive intracellularly or extracellularly in the host, can activate MHC class II (MHCII)-restricted $CD4^+$ T-helper (Th) cells. In addition, certain intracellular bacteria can also activate MHCI-restricted $CD8^+$

cytotoxic T lymphocytes (CTL). Induction of MHCII-restricted T cells requires processing by an exogenous route. After binding to specific cell-surface receptors on macrophages and DCs, and uptake into APCs via opsonization, phagocytosis, or receptor-mediated endocytosis, the bacterial antigens are degraded in endosomes or early lysosomes, and digested peptides, 7–20 amino acids long, associate with newly formed or recycled MHCII molecules before being exported to the cell surface. Induction of class I-restricted CTLs is dependent on bacterial antigens entering the endogenous route of antigen processing, usually through their escape from vacuoles/endosomes into the cytoplasm. Many of the intracellular steps of antigen processing are targets of immune evasion by pathogenic bacteria.

Class I-restricted CTLs kill host cells infected with intracellular bacteria, whereas the main function of class II-restricted $CD4^+$ T cells is to release cytokines that activate phagocytosis and killing of bacteria by macrophages, and to provide helper function for antibody production. $CD4^+$ T cells can be divided into a number of functionally distinct subtypes discriminated on the basis of cytokine secretion. Th1 cells secrete interferon-γ (IFN-γ) and tumor necrosis factor-β (TNF-β), activate phagocytosis and killing by macrophages, and provide help for the production of opsonizing (murine IgG2a) antibodies. Th2 cells secrete interleukins IL-4, IL-5, IL-6, IL-9, IL-10, and IL-13 and are considered to be the main helper cells, especially for immunoglobulin (Ig) IgG1, IgA, and IgE. A further subtype of $CD4^+$ T cells, which secrete high levels of IL-10 and/or transforming growth factor (TGF)-β but not IL-4 or IFN-γ, termed regulatory T (Tr) cells, have recently been described during infection with certain pathogens, including bacteria (McGuirk and Mills 2002). Tr cells have suppressive function and may be induced by the host to turn off immune responses, especially Th1 responses, once the bacteria are eliminated and thereby limit immunopathology. Alternately their induction may serve as an evasion strategy by the bacteria to suppress protective Th1 responses.

Although cell-mediated immunity is important in controlling intracellular bacteria, humoral immunity plays a major role in protection against extracellular bacteria. Antibodies help to prevent infection or to eliminate bacteria in a number of ways, and antibodies of different classes and subclasses perform different functions. Extracellular bacteria often bind to epithelial cells in the respiratory or gastrointestinal (GI) tract via adhesins or pili; antibodies against these bacterial virulence factors can help to prevent colonization. The diseases caused by many bacteria are mediated by toxins; antibodies, especially those of the murine IgG1 subclass, can neutralize these toxins and prevent their binding to host target cells, and thereby reduce the severity of disease. Antibodies of the murine IgG2a subclass can promote phagocytosis by opsonizing the bacteria and stimulating complement components C3b and iC3b, which bind complement receptors and further promote phagocytosis. IgA antibodies, induced after bacterial infection of the respiratory tract, GI tract, or other mucosal tissues, function to limit the infection to mucosal surfaces. In an immune individual primed by a selflimiting infection or immunization, antibodies probably play the major role in conferring protective immunity. Almost all bacterial vaccines in use today confer protection by the generation of circulating IgG or memory B cells, which produce an anamnestic antibody response after re-exposure to the bacteria. However, the generation of antibody responses is also dependent on priming of helper T cells, so both T and B cells are critical in the primary as well as the secondary response to bacterial infection. Bacteria have also evolved strategies to circumvent humoral immunity, either by directly cleaving the antibody molecule or by interfering with the functions of B or Th cells.

EVASION OF PHAGOCYTIC KILLING

Phagocytosis provides a specialized mechanism for ingestion and intracellular destruction of microbial pathogens by neutrophils and macrophages (Aderem and Underhill 1999). These include receptors for the opsonic immunoglobulin Fc domain (e.g. FcγR) and the C3b and C3bi complement fragments (e.g. CR3). FcγRs cluster when bound to an IgG-coated bacterium and become phosphorylated by Src tyrosine kinases. Downstream events include activation of the small GTPases, Rac, and Cdc42, which results in polymerization of actin to form an actin cup at the site of bacterial binding to the plasma membrane, followed by the appearance of F-actin-rich membrane ruffles and internalization of the bound particle surrounded by a lipid bilayer membrane and a halo of actin. CR3-mediated phagocytosis is similar to FcγR-mediated phagocytosis in many ways, but uses Rho GTPases instead of Rac and Cdc42. In addition, CR3-mediated phagocytosis does not induce inflammatory mediators.

Together with internalization of the target, intracellular signaling stimulates interaction of the phagosome with the endocytic network, activates the production of reactive oxygen intermediates (ROI) and enhances the expression of specific genes, especially those encoding cytokines (Duclos and Desjardins 2000; Tjelle et al. 2000). The newly formed phagosomes are immature organelles unable to kill or degrade microorganisms and, in order to acquire and exert their microbicidal function, phagosomes must engage in a maturation process referred to as phagolysosome biogenesis. Phagosomes fuse transiently and sequentially with endosomes of increasing age or of increasing maturation level (early endosomes, late endosomes, and lysosomes). The Rab GTPases are associated with different stages in the fusion pathway: Rab5 enables fusion of the phagosome

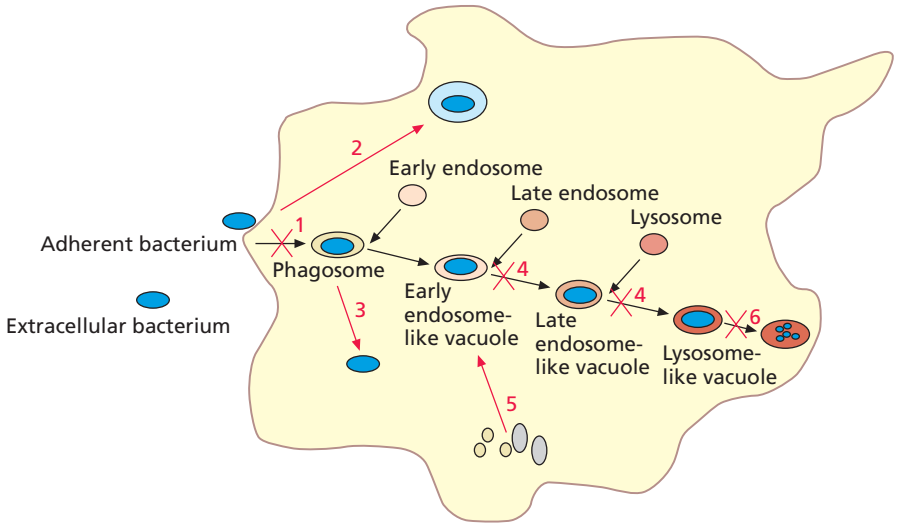

Figure 2 *Evasion of phagocytic killing. Phagocytic cell receptors recognize and bind microorganisms on the cell surface. The bacteria are taken up into phagosome vesicles originating from the plasma membrane. Phagosomes mature by fusing transiently and sequentially with endosomes of increasing age and maturation (early endosomes, late endosomes, and lysosomes). Eventually a phagolysosome is formed with an acidic and lytic compartment to kill, degrade, and further process microorganism antigens for presentation at the cell surface. Bacteria have developed a number of strategies to evade killing by phagocytic cells including: (1) inhibition of phagocytic uptake, (2) bacteria-mediated invasion into a nonlysosomal pathway, (3) escape to cytosol, (4) inhibition of endosomal and lysosomal fusion, (5) fusion with nonlysosomal organelles, and (6) resistance to lysosomal killing.*

with early endosomes, whereas Rab7 allows phagosome fusion with late endosomes. During the maturation process phagosomes acquire markers of late endosomes and lysosomes including the proton pump adenosine triphosphatase (ATPase), nicotinamide adenine dinucleotide phosphate (NADPH) oxidase complex, MHCII molecules, various hydrolases including several cathepsins, and specific antimicrobial pore-forming peptides. In addition, maturing phagosomes acquire Nramp1, which transports divalent cations and modulates intraphagosomal iron content. The combination of reactive oxygen and nitrogen, acidic pH, pore-forming peptides, iron imbalance, and hydrolytic enzymes in the final phagolysosome provides a highly effective antimicrobial combination that is capable of killing a wide variety of bacteria, and further degrading and processing the microorganism antigens for presentation at the cell surface. Bacteria have developed a number of strategies to evade killing by phagocytic cells (Figure 2).

Inhibition of chemotaxis

Pathogens can prevent killing by neutrophils and macrophages through the inhibition of the migration of these phagocytic cells to the site of infection. Cell chemotaxis is controlled by inflammatory cytokines and chemokines, and complement components, and through the expression of adhesion molecules on the cell surface; each of these regulatory mechanisms can be targeted by a number of pathogens. Pneumolysin, a sulfhydryl-activated toxin produced by *Streptococcus pneumoniae*, can inhibit chemotaxis of human polymorphonuclear cells (Paton and Ferrante 1983). The peptidoglycan fraction of staphylococci induces production of an inhibitory protein by mononuclear cells that inhibits neutrophil chemotaxis and the bacterial peptide *N*-formyl-Met-Leu-Phe inhibits neutrophil migration and killing of *Staphylococcus epidermidis* (Donabedian 1985; Li et al. 2002b).

The AB toxin, pertussis toxin (PT), plays a major role in *Bordetella pertussis* pathogenesis. Binding of the B-oligomer to host cells allows the A subunit to enter the cell, where adenosine diphosphate (ADP)-ribosylation of G_i proteins that transmit inhibitory signals to the adenylyl cyclase complex occurs, resulting in elevated intracellular cyclic adenosine monophosphate (cAMP), which affects signaling pathways in many cell types, including cells of the immune system; this contributes to immune dysfunction. PT has been shown to inhibit macrophage chemotaxis in vivo (Meade et al. 1985) and neutrophil and lymphocyte chemotaxis in vitro by altering intracellular calcium levels (Spangrude et al. 1985). Recent evidence has shown that the leukocytosis induced by PT may result from G-protein-dependent, chemokine-regulated extravasion of leukocytes. PT inhibits the increase in intracellular Ca^{2+} levels in $CD4^+$ and $CD8^+$ T cells, induced by the CC chemokines, macrophage chemoattractant protein 1 (MCP-1), MCP-2, MCP-3, macrophage inflammatory protein 1α (MIP-1α), MIP-1β, and RANTES (Loetscher et al. 1994), Ca^{2+}-mediated activation of neutrophils induced by IL-8 (Schorr et al. 1999), and MCP-1-induced chemotaxis of NK cells (Allavena et al. 1994).

Inhibition of phagocytic uptake

Successful extracellular bacteria have the ability to inhibit uptake by phagocytic cells (Ernst 2000). *Yersinia* spp. share a common mechanism to inhibit phagocytosis by macrophages (Cornelis et al. 1998). These bacteria and a number of other virulent gram-negative animal and plant pathogens possess a dedicated pathogenicity secretion system called a type III secretion system (TTSS), which is responsible for directly delivering effector molecules from the bacterium into the eukaryotic cytosol. These effectors interfere with normal immune cell function, primarily disrupting signal transduction pathways and cytoskeleton arrangements. *Yersinia* spp. express a number of TTSS effectors that inhibit phagocytic uptake, one of which is YopH which after entry into the cell cytoplasm rapidly blocks phagocytosis through Fcγ receptors (Grosdent et al. 2002). YopH is a tyrosine phosphatase that dephosphorylates focal adhesion kinase (FAK) and $p130^{Cas}$. These proteins are found at sites of focal adhesions and are thought to play an important role as adaptor proteins during phagocytosis (Black and Bliska 1997; Persson et al. 1997). A second *yersinia* TTSS effector, YopE, acts together with YopH to inhibit phagocytosis (Rosqvist et al. 1988). YopE is a GTPase-activating protein that selectively increases GTP hydrolysis by RhoA, Rac, and Cdc42, key regulators of actin cytoskeleton dynamics, thereby inactivating them (Von Pawel-Rammingen et al. 2000). The TTSS effector ExoS of *Pseudomonas aeruginosa* acts in a similar manner to disrupt actin filaments and inhibit phagocytosis (Pederson et al. 1999).

Enteropathogenic *Escherichia coli* (EPEC) inhibits FcγR-mediated macrophage phagocytosis but not CR3-mediated phagocytosis via its TTSS (Celli et al. 2001). This is the result of inactivation of phosphatidyl inositol (PI)-3-kinase, leading to inhibition of pseudopod extension and complete phagocytic cup formation. *Helicobacter pylori* expresses another kind of secretion system associated with pathogenic processes – a type IV secretion system. This secretion system also delivers effector molecules into the eukaryotic cell and is responsible for inhibition of bacterial uptake by phagocytic cells (Ramarao et al. 2000). *Mycobacterium tuberculosis* and/or its lipoarabinomannan downregulates macrophage activation, and thereby phagocytosis, by stimulation of SHP-1, a cytosolic protein tyrosine phosphatase (Nandan et al. 2000).

Bacteria-mediated invasion into phagocytic and nonphagocytic cells

Some pathogens survive by living intracellularly in eukaryotic cells. In this way the bacteria avoid recognition by soluble factors, such as complement and antibody, and by immune cells. The bacteria direct their own uptake into nonphagocytic cells and/or phagocytic cells via receptors other than Fc receptors, and in this way bacteria avoid triggering activation of the intracellular bacterial killing mechanisms, so that the bacteria can survive and replicate safely within the cell.

Invasion is initiated by binding of the bacteria to the eukaryotic cell surface. This adhesion is mediated by bacterial adhesins and/or invasins binding to specific receptors on the cell surface. The invasin–receptor interaction then triggers uptake of the bacteria. One set of receptors on eukaryotic cells that is often used by bacteria to enter cells is the integrins (Isberg et al. 2000), which are large heterodimeric transmembrane proteins that are capable of transmitting signals to the cell cytoskeleton after adhesion to substrates. The invasin protein of *Yersinia enterocolitica* uses this receptor to pass through M cells from the gut to the underlying tissue. Bacterial attachment initiates receptor clustering to direct signaling for cytoskeleton rearrangements and entry, a process in which FAK and Rho GTPases are involved. The internalin protein of *Listeria monocytogenes* binds E-cadherin, a cell surface protein involved in cell–cell interactions, and the *Neisseria* family of Opa proteins bind the CD66 family of receptors (Mengaud et al. 1996). Receptors can also be glycosaminoglycans and extracellular matrix proteins such as fibronectin (Joh et al. 1999).

Bacteria can subvert complement for invasion of eukaryotic cells. In contrast to FcγR-induced phagocytosis, complement–induced phagocytosis does not provoke a respiratory burst, nor does it induce inflammatory mediators (Caron and Hall 1998), so the bacteria bypass powerful cellular killing mechanisms, such as H_2O_2 and oxygen free radicals. Deposition of complement on the cell surface allows bacteria, such as *Legionella pneumophila*, to enter host cells via C receptors (Cooper 1991). Alternately, bacteria can enter cells via complement receptors independently of complement itself, such as *E. coli* via Dr adhesins (Pham et al. 1997). Several bacteria use CR3 for intracellular entry, e.g. filamentous hemagglutinin (FHA) of *B. pertussis* (Ishibashi et al. 1994). *M. tuberculosis* binds CR1 and CR3 to enhance its uptake into cells and InlB of *L. monocytogenes* mediates bacterial entry via gC1q-R/p32, a C1q-binding protein (Braun et al. 2000; Schlesinger et al. 1990).

Bacteria can induce their internalization via subversion of actin skeleton arrangements, a process that is often dependent on TTSS effectors (Steele-Mortimer et al. 2000). Entry of *Salmonella* and *Shigella* spp. into eukaryotic cells is determined by actin polymerization at the site of bacterial contact with the cell membrane and, at the peak of extension formation, numerous cytoskeleton proteins are recruited which form the entry foci. The TTSS effectors of *Salmonella* and *Shigella* spp. first interact with specific cytoskeleton proteins to depolymerize actin filaments and microtubules to allow

rearrangement of the cytoskeleton components for mediating bacterial entry. The effectors then activate Cdc42 and Rac1 GTPases to induce actin polymerization and stabilize the newly formed cytoskeleton structure to engulf the bacteria.

The mode of entry of the bacteria into the eukaryotic cell will influence their trafficking along the phagolysosomal pathway and the signaling cascades that are activated. Thus, the receptor that mediates particle internalization and the nature of the internalized particle play an important role in phagosome maturation and phagosome–lysomal fusion.

Escape into cytoplasm

Bacteria such as *Listeria* spp., *Rickettsia* spp., enteroinvasive *E. coli*, and *Shigella* spp. lyse the primary phagosome and enter the cytoplasm where they can safely replicate (Goebel and Kuhn 2000). Entry of bacteria into the cytosol is achieved by the action of phospholipases and pore-forming toxins; the mechanism employed by *Listeria* spp. has been studied best. Escape from the phagosome is necessary for intracellular survival and proliferation of *L. monocytogenes*, a process in which the pore-forming cytolysin listeriolysin O (LLO) plays an essential role (Vazquez-Boland et al. 2001). LLO is active only at low pH and thus it specifically lyses the phagosomal membrane when it is released by the bacteria in the phagosome, and not the plasma membrane of the cell, because after vacuole lysis the pH equilibrates and LLO is deactivated (Beauregard et al. 1997). LLO forms holes in the phagosomal membrane allowing access of the bacteria's own phospholipases, or even cellular lipases, to the phagosomal membrane, which result in the subsequent membrane disruption (Smith et al. 1995).

Inhibition of lysosomal fusion

After uptake into the phagosome several bacterial pathogens have the ability to halt maturation of the vacuole, and trafficking to late endosomal and lysosomal compartments by inhibiting endosome–lysome fusion. *Salmonella typhimurium* traffics to an early endosome-like vacuole that does not mature into a lysosome-like vacuole, where the bacteria grow and multiply (Gorvel and Meresse 2001). Direct interaction of the vacuole containing the *Salmonella* with late endosomal compartments is inhibited (Meresse et al. 1999) and TTSS effectors of *Salmonella* are involved in this inhibition of phagosome–lysosome fusion (Uchiya et al. 1999). These effectors are also necessary to prevent the trafficking of the NADPH oxidase complex to the *Salmonella*-containing vacuole (Vazquez-Torres et al. 2000).

Mycobacterium tuberculosis also inhibits lysosomal delivery. The vacuole containing *Mycobacterium* lacks late endosomal markers and retains Rab5, but not Rab7, thus implicating a block between early and late endosomal fusion (Via et al. 1997). A molecule called TACO (coronin 1) is actively retained at the mycobacterial phagosome membrane limiting interaction with endocytic organelles, and allowing *Mycobacterium* to survive within the phagosomes (Ferrari et al. 1999). Phagosomes containing *Mycobacterium* also lack V-ATPase, thereby preventing acidification (Sturgill-Koszycki et al. 1994).

Chlamydia spp. express proteins that modify the vacuole to ensure that trafficking of bacteria is diverted away from the endocytic pathway to the exocytic pathway (Hackstadt et al. 1997; Wyrick 2000). The vacuole interacts with vesicles derived from the trans-Golgi protein trafficking network en route to the cell surface and thus acquires sphingomyelin. It also acquires phosphatidylcholine and PI from the endoplasmic reticulum (ER) and cardiolipin from the mitochondria, so that the vacuole is thus camouflaged and does not interact with lysosomal compartments (Wylie et al. 1997). Chlamydial proteins IncA–G are also incorporated into the vacuole membrane and may be involved in inhibition of vacuole maturation (Scidmore-Carlson et al. 1999).

Transport to nonlysosomal organelles

Instead of trafficking to the endosomal pathway, virulent *Brucella abortus*, *L. pneumophila*, and *Porphymonas gingivalis* traffic to autophagosome-like vacuoles (Dorn et al. 2002). Autophagy is a cellular process for the degradation of organelles and cellular compartments, resulting in breakdown products that are recycled for the synthesis of new components. The nascent autophagosome is a vacuole derived from the rough ER, and contains organelles and undegraded cytoplasmic substances that had been selectively or nonselectively sequestered within the autophagosome. This early autophagosome matures to an acidic late autophagosome lacking hydrolytic enzymes, which then docks and fuses with a lysosome-containing acid proteases. The sequestered cellular components are then degraded and recycled.

Early after infection *Brucella*-containing phagosomes transiently fuse with early endosomes; however, they do not display Rab7 and do not fuse with lysosomes or late endosomal compartments (Pizarro-Cerda et al. 1998). Instead they acquire ER and autophagosomal characteristics, perhaps by fusion with an early autophagosome. Eventually *Brucella* transits from the autophagosome to the ER, where bacterial replication occurs. In this niche the bacteria not only avoid degradation but also obtain a supply of metabolites. The type IV secretion system of *Brucella* sp. is essential for the biogenesis of the autophagosome-like vacuole and for intracellular survival and replication (Comerci et al. 2001). In the absence of a

functional type IV secretion system *Brucella* fails to evade the endocytic pathway and is instead targeted to lysosomes for subsequent degradation.

On entry into cells, vacuoles containing *Legionella* sequentially associate with smooth vesicles, mitochondria, and the ER (Horwitz 1983). The vacuoles fail to acquire late endosomal/lysosomal markers, fail to acidify, and are competent for bacterial replication. They are similar to autophagic vacuoles. This process is also controlled by a type IV secretion system, called dot/icm (Roy et al. 1998).

Resistance to lysosomal killing

Pathogenic bacteria have the ability to survive within phagolysosomes. The acidity of these vacuoles is a major obstacle for the bacteria to overcome. Some pathogens can survive in this acidic environment, whereas others attenuate the acidic pH. *Coxiella* spp. survive and multiply in mature lysosomes where they avoid digestion by lysosomal enzymes and actually require the acidic environment to stimulate metabolism and growth (Heinzen et al. 1996). *Bordetella bronchiseptica* can survive the acidic environment in the lysosome and replicate intracellularly, whereas *B. pertussis* cannot (Schneider et al. 2000). In contrast *Mycobacterium* maintain a neutral pH by retaining endosomal Na^+/K^+ ATPase, as do *Chlamydia* (Sturgill-Koszycki et al. 1994; Schramm et al. 1996).

Reactive oxygen species are generated by the respiratory burst in the macrophage vacuoles to kill intracellular bacteria (Hampton et al. 1998; Zahrt and Deretic 2002). The respiratory burst is caused by the NADPH oxidase complex, which assembles at the phagolysosomal membrane. Electrons are transferred from cytoplasmic NADPH to oxygen on the phagosomal side of the membrane, generating superoxide plus a range of other ROIs with toxic bactericidal activity.

Bacteria have many mechanisms for protection against ROIs. Some involve the production of enzymes to inactivate these molecules. *S. typhimurium* expresses superoxide dismutases, enzymes that catalyze the formation of hydrogen peroxide from superoxide anion and which contribute significantly to *Salmonella* virulence (De Groote et al. 1997; Farrant et al. 1997). Superoxide dismutase also protects *M. tuberculosis* from respiratory burst killing (Piddington et al. 2001). Catalases in turn detoxify hydrogen peroxide to water. The *Salmonella* catalase SodC and the *Campylobacter jejuni* KatA enhance survival toward the respiratory burst (De Groote et al. 1997; Day et al. 2000). In addition, several scavenging enzymes including glutathione reductase and thioredoxin reductase use reducing equivalents from NADPH either to generate low-molecular-weight antioxidant species or to repair oxidative lesions. DNA repair enzymes are required for *Salmonella* survival in mice and for resistance to the respiratory burst, because DNA is a critical bacterial target for reactive oxygen (Buchmeier et al. 1993). The production of ROIs can be inhibited by preventing NADPH oxidase complex formation in the vacuole membrane. *Ehrlichia* sp. inhibit superoxide production by downregulating expression of the NADPH oxidase complex component $gp91^{phox}$ (Banerjee et al. 2000) and *L. pneumophila* inhibits protein kinase C which is necessary for the mobilization of cytosolic NADPH phagocyte oxidase components to the membrane (Jacob et al. 1994).

Reactive nitrogen intermediates (RNI) are also formed in the lysosome by inducible nitric oxide synthase (iNOS). Resistance to RNIs can be mediated by the scavenger enzymes that also confer resistance to ROIs (Zahrt and Deretic 2002). It remains unclear whether bacteria have a dedicated RNI resistance mechanism, or whether resistance is the result of coordinated expression of multiple survival-related pathways.

MODULATION OF PRO- AND ANTI-INFLAMMATORY CYTOKINE PRODUCTION

Bacterial activation of cells of the innate immune system

Macrophages, DCs, NK cells, and nonconventional T cells, including NKT cells and γδ T cells, all function in immunity to bacterial infections, either by uptake and killing of the bacteria, lysis of infected host cells, presentation of antigens to T cells, or release of cytokines that activate antibacterial activity of other cells, or by regulating the adaptive immune responses to the bacteria. The immediate inflammatory response to bacterial infection involves the production of proinflammatory cytokines, including TNF-α, IL-1β, IL-12, and IL-18, and chemokines, including MIP-1α MIP-1β, MIP-2, and RANTES, largely by cells of the innate immune system. These cytokines and chemokines recruit leukocytes to the site of infection, activate their antimicrobial function, and in addition regulate the induction of the adaptive response to the bacteria. IL-12 and IL-27 promote the differentiation of Th1 cells, which mediate cellular immunity against intracellular bacteria and also stimulate the production of opsonizing and complement-fixing antibodies. This proinflammatory response is beneficial to the host in eliminating the bacteria, but is also responsible for many undesirable systemic and central effects, including fever and sepsis, which if uncontrolled can cause immunopathological damage to host tissues. The induction of anti-inflammatory cytokines by the bacteria, especially IL-10 and TGF-β, helps to suppress inflammation, but can also be exploited by the bacteria to turn off protective immune responses.

Bacteria stimulate cells of the innate immune system through interaction of conserved bacterial molecules with receptors on the host cells. Whole bacteria and specific bacterial products, termed pathogen-associated molecular patterns (PAMP), including lipopolysaccharide (LPS), CpG motifs in bacterial DNA, and peptidoglycan, bind to PRRs, which include but are not exclusively Toll-like receptors (TLR), expressed on a variety of cells, e.g. macrophages and DCs (Guermonprez et al. 2002). Differential expression of TLRs and other PRRs on distinct DC subtypes determine the response to different PAMPs (Janeway and Medzhitov 2002). Plasmacytoid DCs selectively expressed TLR-7 and TLR-9 and respond to bacterial CpG motifs, whereas myeloid DCs express all TLRs except TLR-7 and TLR-9, and do not respond to CpG, but are stimulated by LPS and peptidoglycan, which bind to TLR-4 and TLR-2, respectively (Jarrossay et al. 2001). Binding to TLRs activates signaling through NF-κB, leading to the production of inflammatory cytokines including IL-12, TNF-α, IL-1β, IL-6, and IL-18, and the increased surface expression of maturation markers on DCs. The same bacteria can also stimulate the production of anti-inflammatory cytokines, IL-10, TGF-β, and IL-1 receptor antagonist (IL-1ra), either using the same or distinct conserved structures, which bind to and activate distinct signaling receptors and pathways.

Suppression of IL-12 and TNF-α production

Suppression of proinflammatory cytokine production, especially IL-12 and TNF-α, either through induction of IL-10 or through interference with steps in the NFκB signaling pathways is a common strategy employed by bacteria to subvert macrophage activation and induction of Th1 responses. *B. pertussis* FHA suppresses IL-12 by macrophages and DCs and the suppression is mediated by the induction of IL-10 production (McGuirk and Mills 2000; McGuirk et al. 2002). Furthermore FHA suppressed IL-12 and IFN-γ production in vivo in response to LPS in a model of septic shock and suppressed influenza virus-specific IFN-γ production when coadministered to mice with influenza virus by the nasal route (McGuirk et al. 2002).

The AB-type toxins cholera toxin (CT) and *E. coli* heat-labile enterotoxin (LT), also modulate the production of regulatory cytokines and chemokines by cells of the innate immune system. CT, LT and the partially toxic mutant LTR72 suppress production of IL-12 and TNF-α and of the inflammatory chemokines, MIP-1α and MIP-1β (Lavelle et al. 2003; Ryan et al. 2000). Furthermore, CT inhibits the production of bioactive IL-12 (p70) and the expression of the β1 and β2 chains of the IL-12 receptor on human monocytes and DCs, leading to a suppression of Th1 cell differentiation and a predominantly Th2-type response (Braun et al. 1999b). Similarly, exposure of human DCs to CT inhibits IL-12p70, TNF-α, but not IL-6, IL-8, or IL-10 secretion in response to LPS or CD40 ligand (Gagliardi et al. 2000). A mutant of LT devoid of ADP-ribosylating activity does not inhibit IL-12 or TNF-α, suggesting that the enzyme activity is responsible for the suppression. Intracellular cAMP induced by active CT and LT appears to affect signaling pathways within the cells involved with IL-12 and TNF-α production. Furthermore, accumulation of intracellular cAMP directly inhibits cytokine production by Th1 cells and enhances Th2 cells (Ryan et al. 2000).

Another ADP-ribosylating toxin, anthrax edema toxin from *Bacillus anthracis*, inhibits LPS-induced TNF-α, and IL-6 production in human monocytes by increasing intracellular cAMP levels (Hoover et al. 1994). Furthermore, exotoxin A from *P. aeruginosa*, which also has ADP-ribosylating activity, inhibits release of TNF-α, TNF-β, IFN-γ, IL-1β, and IL-1α from both macrophages and lymphocytes (Staugas et al. 1992; Braun et al. 1999b). TNF-α production is also suppressed at the site of infection and in Peyer's patches of mice infected with *Y. enterocolitica*; the YopB protein from this bacteria was found to inhibit TNF-α production, but not other inflammatory cytokines, such as IL-1β and IL-6, by murine macrophages in vitro (Beuscher et al. 1995). Suppression of TNF-α production by *Y. enterocolitica* was associated with inhibition of NF-κB activation (Ruckdeschel et al. 1998). High-molecular-weight proteins released by *Brucella suis* inhibit TNF-α production by human macrophages infected with *E. coli* (Caron et al. 1996). Other bacteria, including *M. tuberculosis*, *Lactobacillus reuteri*, and *Histoplasma capsulatum*, suppress macrophage IL-12 production, but the bacterial molecules involved have not been identified (McGuirk and Mills 2002).

Induction of IL-10 and TGF-β production

A number of bacteria, including *Mycobacterium* spp., *L. pneumophilia*, *S. typhimurium*, *L. monocytogenes*, and *Y. enterocolitica*, stimulate IL-10 production by macrophages (Redpath et al. 2001). In a limited number of cases the bacterial molecule responsible has been identified. FHA, an adhesin from *B. pertussis* that binds to CR3 (Ishibashi et al. 1994), induces IL-10 and IL-6 production by macrophages and DCs (McGuirk and Mills 2000; McGuirk et al. 2002). The induction of IL-10 production was linked to suppression of IL-12, induction of Tr cells and suppression of Th1 responses in the lungs and local lymph nodes of *B. pertussis*-infected mice.

The immunosuppression associated with *M. tuberculosis* and the suppressed IFN-γ production in TB-infected individuals has been attributed to IL-10 and TGF-β production by mononuclear cells, including

macrophages and DCs. Purified protein derivative (PPD) of *Mycobacterium* induces IL-10 and TGF-β production by human mononuclear cells (Toossi et al. 1995; Othieno et al. 1999) and suppresses the production of IFN-γ, whereas neutralization of IL-10 and TGF-β enhances IFN-γ production (Othieno et al. 1999). Naturally occurring inhibitors of TGF-β (latency-associated peptide and decorin) restored in vitro T-cell responses of patients with TB and decreased growth of the bacteria in vitro and in vivo (Hirsch et al. 1997; Wilkinson et al. 2000). However, in a longitudinal study of TB patients, PPD-specific IL-10 and TGF-β production by peripheral blood mononuclear cells (PBMC) returned to baseline levels after 3 months, although PPD-specific IFN-γ production remained depressed for up to 12 months (Hirsch et al. 1999), suggesting that PPD-specific IL-10 and TGF-β are not the only factors involved in the immunosuppression.

Lipoarabinomannan (LAM), a cell wall component of *M. tuberculosis*, induces IL-10 production from human mononuclear cells (Barnes et al. 1992) and TGF-β from human monocytes (Dahl et al. 1996), and this has also been provided as an explanation for the immunosuppressive effects of the bacteria on antigen-induced T-cell proliferation. However, LAM also stimulated production of granulocyte–macrophage colony-stimulating factor (GM-CSF), IL-1, IL-6. and IL-8 (Barnes et al. 1992), suggesting that it had pro- as well as anti-inflammatory effects. Infection of macrophages with *M. tuberculosis* induces the production of IL-10, IL-1, IL-6, IL-18, and TNF-α, but not IL-12 except in the presence of anti-IL-10 antibody. In contrast, infected DCs secrete IL-12, IFN-α, and TNF-α, but not IL-10 (Giacomini et al. 2001). It was suggested that the differential responses of the cells related to their distinct functions in infection, macrophages establishing inflammation inside granulomas and DCs directing T-cell responses in the draining lymph nodes. It has also been demonstrated that infection of DCs with *M. bovis* BCG induces release of IL-10 and IL-12, and that infected DCs from IL-10-deficient (IL-$10^{-/-}$) mice are more effective at trafficking to the lymph nodes, secrete higher levels of IL-12, and induce higher IFN-γ levels in response to mycobacterial antigens than wild-type DC (Demangel et al. 2002). An analogous finding has been reported for *Chlamydia trachomatis*, where modulation of endogenous IL-10 production by using IL-$10^{-/-}$ mice or antisense IL-10 enhances the ability of APCs to induce *Chlamydia*-specific Th1 responses (Igietseme et al. 2000). This suggests that upregulation of IL-10 production by DCs may serve as a strategy by the pathogen to turn off protective Th1 responses, and that inhibition of IL-10 production by APCs may provide a strategy for therapy or immunization against these diseases.

The virulence of *M. tuberculosis* strains has been linked to their ability to induce IL-10 production, with certain clinical isolates stimulating the highest level of this cytokine from human macrophages (Barnes et al. 1992). Another consequence of monocyte/macrophage IL-10 production by *M. avium* is the induction of soluble TNF receptor 2 (sTNFR2), which can inactivate TNF-α and block TNF-α-induced apoptosis (Balcewicz-Sablinska et al. 1998). Apoptosis of infected cells is a host defense measure to prevent intracellular multiplication of bacteria and this can be circumvented by *M. tuberculosis* and other bacteria (see below under Apoptosis).

There is also evidence from other bacterial species linking virulence to the ability to stimulate IL-10 or TGF-β production. The virulence-associated V antigen (LcrV) of pathogenic *Yersinia* spp. induces IL-10 release from mouse and human macrophages and as a consequence inhibits TNF-α production (Sing et al. 2002). It has been suggested that replication of *Coxiella burnetii* and the development of chronic Q fever may be facilitated by the induction of IL-10 production in macrophages; *C. burnetii* stimulates IL-10 and inhibits TNF-α production by monocytes and bacterial replication is inhibited by neutralizing anti-IL-10 antibodies (Ghigo et al. 2001). Lipidated outer surface protein A (L-OasA) from *Borrelia burgdorferi*, the etiological agent of Lyme disease, induces IL-10 production by human monocytes (Giambartolomei et al. 1998). Inhibition of endogenous IL-10 production with anti-IL-10 inhibits IL-12 and IL-6 antibodies but not IL-1β or TNF-α; this has been explained by a difference in the kinetics of cytokine production by monocytes in response to *B. burgdorferi*, with TNF-α production peaking within 1 h, followed by IL-10 and IL-1β, whereas IL-6 and IL-12 were produced later (Murthy et al. 2000). Inhibition of endogenous or bacteria-stimulated TGF-β2 production in mice infected with *L. monocytogenes* enhances IFN-γ, TNF-α, and IL-12 production and increases survival of the mice (Szalay et al. 1999). Although the source of the TGF-β has not been identified, it has been suggested that it may be derived from γδ T cells, NKT cells, or other cells of the innate immune system. In contrast, injection of anti-TGF-β1 diminishes resistance to *L. monocytogenes*, whereas administration of TGF-β1 protected mice from the infection (Nakane et al. 1996)

Studies in cytokine knock-out mice have provided more definitive evidence of a role for endogenous or bacteria-stimulated IL-10 production on the course of bacterial infections. In certain cases infection is less severe in IL-$10^{-/-}$ mice, confirming that this cytokine may help to subvert protective immunity by suppressing innate and adaptive immune responses, e.g. IL-$10^{-/-}$ mice are highly resistant against infection with *Yersinia* spp. and the bacteria-dependent suppression of TNF-α, mediated by IL-10, was absent in the knock-out mice (Sing et al. 2002). Cell-mediated immunity to *M. bovis* BCG is enhanced in IL-$10^{-/-}$ mice and the knock-out mice eliminate the bacteria faster than wild-type (Jacobs et al. 2000).

However, in other infections, the severity of disease is exacerbated in IL-$10^{-/-}$ mice, suggesting that IL-10 has a protective role, possibly by limiting immune-mediated pathology. IL-$10^{-/-}$ mice succumb to primary and secondary infection with *L. monocytogenes*; the number of cells in the inflammatory infiltrate, the inflammatory cytokine production in the brain and the severity of brain lesions is enhanced in the knock-out mice (Deckert et al. 2001). Although the numbers of bacteria were not significantly different between wild-type and IL-$10^{-/-}$ mice infected with *L. monocytogenes*, there are also examples of bacterial infection in IL-$10^{-/-}$ mice where disease pathology is enhanced or where bacterial clearance is accelerated. Peritonitis and mortality from *E. coli* infection is enhanced in IL-$10^{-/-}$ mice, despite accelerated clearance of the bacteria in knock-out compared with wild-type mice (Sewnath et al. 2001). The colonization of the gastric mucosa by *H. pylori* is reduced in IL-$10^{-/-}$ mice, but the severity of chronic active gastritis is significantly higher than in the wild-type mice (Chen et al. 2001). Similarly, IL-$10^{-/-}$ mice infected with *Helicobacter hepaticus* develop severe inflammation associated with IL-12 production and Th1 responses (Kullberg et al. 2001).

CYTOLYSIS AND APOPTOSIS OF MACROPHAGES, DCS, AND T CELLS

Apoptosis

Apoptosis or programmed cell death is a normal mechanism to remove unwanted cells from the body and plays a critical role in homeostasis in the immune system. After infection, apoptosis of lymphocytes reduces the pool of effector T and B cells, which have recently expanded through stimulation with foreign antigens. The process is carried out and controlled within the cell by a family of cysteine proteases, called caspases, which cleave cellular proteins and activate other caspases, eventually leading to the dismantling of cellular components. Apoptosis is considered to be a mechanism for removing unwanted cells without inducing an inflammatory response. Phagocytic cells bind dying and apoptotic cells, phagocytose them, and prevent release of their intracellular contents.

Induction or inhibition of apoptosis can influence the outcome of infection. Induction of programmed cell death in cells of the immune system, including T and B lymphocytes, macrophages, and DCs, is a common feature of many bacterial infections and serves as a strategy to eliminate cells directly involved in protective immunity. Induction of apoptosis of macrophages infected with intracellular bacteria serves to prolong infection by hindering bacterial killing and promoting the spread of the bacteria. It has also been proposed that bacteria-induced apoptosis may be a mechanism to initiate tissue damage, and evidence has been reported to link apoptosis to acute colitis associated with shigellosis (Zychlinsky and Sansonetti 1997).

Elimination of immune cells can also be achieved via cytolysis. Cytolysins are pore-forming bacterial toxins that lyse cells by cell membrane disruption. As with apoptosis induction, stimulation of this cell death mechanism enhances bacterial survival by killing cells such as leukocytes, monocytes, and neutrophils. These toxins play a crucial role in virulence as judged by in vivo studies and are important components contributing to severe inflammatory disease in response to bacterial infection. In some instances (often dependent on toxin concentration and target cell type) these toxins induce apoptosis.

Bacterial virulence factors can modulate cell death pathways in a variety of ways including:

1. disruption of membrane integrity and leakage of cellular components by pore-forming bacterial toxins
2. inhibition of host cell protein synthesis by bacterial toxins
3. delivery of effector proteins into host cells by bacterial TTSS, some of which can directly interact with caspases
4. deletion of T cells by bacterial superantigens
5. activation of second messengers by a bacterial effector.

Pore-forming toxins

Pore-forming toxins are released from bacteria as monomers, which then assemble into oligomeric pores in the target eukaryotic cell membrane. The pores lead to enhanced membrane permeability to monovalent ions and ATP release and hence cytolysis. Repeat-in-toxin (RTX) toxins (also called α-hemolysins) are one class of pore-forming toxins that are produced by a number of bacterial species and include Lkt of *Pasteurella haemolytica* and α-hemolysin of *E. coli* (Weinrauch and Zychlinsky 1999). Binding of RTX toxins to β_2-integrins results in pore formation, increases in intracellular calcium, and cytolysis (Jeyaseelan et al. 2000; Lally et al. 1997). Both α- and β-hemolysins of *Staphylococcus aureus* and *Clostridium perfringens* β-toxin are β-barrel pore-forming toxins (Menestrina et al. 2001). There are no known receptors for these toxins, which cause cell lysis via release of K^+ and also cause rapid calcium influx by opening of endogenous channels. Thiol-activated cholesterol-binding cytolysins are produced by gram-positive bacteria and include streptolysin O produced by *Streptococcus* spp. and pneumolysin produced by *S. pneumoniae* (Palmer 2001). These toxins are important for virulence of the invasive diseases caused by *Streptococcus* spp. They specifically require cholesterol for membrane insertion and act on any cell

type displaying this molecule (Shany et al. 1974; Ohno-Iwashita et al. 1992). The pores formed by these toxins are larger than those formed by hemolysis and permit flow of ions, small metabolites, and macromolecules. Even bacterially secreted proteins such as proteases and nucleases can enter the eukaryotic cells via the pores.

Nucleated animal cells may recover from toxin attack by membrane repair mechanisms, and thus low doses of toxin will affect but not kill target cells. Exposure of immune cells to sublethal doses of pore-forming toxins triggers a variety of proinflammatory reactions such as enhanced cytokine release, cytokine receptor shedding, and nitric oxide generation, as a result of stress activation of NF-κB (Hackett and Stevens 1992; Walev et al. 1996; Braun et al. 1999a).

Pore-forming toxins can also induce apoptosis depending on the toxin structure, toxin concentration, and target cell type. The RTX toxins induce apoptosis by perturbation of mitochondrial structure and function, and by activating caspase-3 and caspase-9 (Guzman et al. 1996; Lally et al. 1997; Korostoff et al. 2000). *L. monocytogenes* kills infected DCs by apoptosis thorough release of listeriolysin O (Guzman et al. 1996). In contrast, *Listeria* spp. do not induce apoptosis in macrophages (Zychlinsky et al. 1992). *B. pertussis* induces apoptosis of macrophages via the activity of adenylyl cyclase hemolysin toxin (AC-Hly) (Khelef et al. 1993; Gueirard et al. 1998). The toxin is a bifunctional protein, with a pore-forming hemolysin domain and an adenylyl cyclase domain that elevates intracellular cAMP. Elevated intracellular cAMP interferes with intracellular signaling in cells of the immune system and modulates a variety of immune effector functions, and also induces apoptosis in macrophages and DCs (Khelef et al. 1993; Gueirard et al. 1998).

Induction of DNA damage and inhibition of host-cell protein synthesis by bacterial toxins

Cytolethal distending toxins (CDT) produced by a variety of bacteria induce apoptosis through DNA damage and it has recently been reported that CDTs from *Haemophilus ducreyi* induce apoptosis in immature, but not mature, DCs (Li et al. 2002a). Apoptosis of HeLa cells by CDTs is associated with phosphorylation of histone H2AX and relocation of the DNA repair Mre11 complex (Li et al. 2002a). Diphtheria toxin (DT) from *Cornyebacterium diphtheria* induces macrophage apoptosis by binding to elongation factor 2 and inhibiting translation; mutant toxins deficient in ADP-ribosylating activity are not cytotoxic (Chang et al. 1989; Morimoto and Bonavida 1992). It has also been suggested that DT has nuclease activity, which may contribute to apoptosis by causing DNA fragmentation (Chang et al. 1989).

CT and LT induce apoptosis in T cells, especially $CD8^+$ T cells. Some reports have suggested that the proapoptotic effect of CT is linked to the ADP-ribosyltransferase activity of the S-1 subunit and increased intracellular cAMP (Yamamoto et al. 1999). However, others have shown that the recombinant B subunit of LT can also induce apoptosis in $CD8^+$ T cells by activating the transcriptional factor c-Myc and caspase-3 via a pathway involving NF-κB (Soriani et al. 2001; Salmond et al. 2002).

Products of type III secretion system interacting with caspases

Shigella spp. induces apoptosis of macrophages but not of other cell types. After phagocytosis of *Shigella* by macrophages it escapes from the phagosome into the cytoplasm, inducing apoptosis (Zychlinsky and Sansonetti 1997). The TTSS effector IpaB of *Shigella* sp. induces apoptosis by binding to and activating caspase-1 (Hilbi et al. 1998). Macrophage apoptosis induced by *Shigella flexneri* is associated with release of IL-1 and IL-18, which require caspase-1 for their activation. Caspase-1-deficient mice do not develop acute inflammation that is normally associated with *Shigella* infection, but they are unable to resolve the infection (Sansonetti et al. 2000). *Salmonella* spp. also induce apoptosis in infected macrophages and the mechanism appears to involve the TTSS and is similar to that described for *Shigella*. Although *Salmonella* sp. does not escape the phagolysosome, the SipB effector protein of *Salmonella* like IpaB of *Shigella*, associates with and activates caspase-1 (Hersh et al. 1999).

The establishment of infection by *Yersinia* spp. is dependent on the TTSS which encodes several Yop effectors; these interfere with the function of cells of the immune system. It has been reported that YopJ/YopP is essential for inducing apoptosis in vivo and in cultured macrophages (Monack et al. 1997, 1998). Induction of apoptosis, together with suppression of TNF-α production, facilitates the establishment of *Yersinia* infection in mice (Beuscher et al. 1995). YopP/YopJ induces apoptosis by impairing NF-κB signaling via binding and inhibiting IKKβ, the NFκB-controlling protein (Ruckdeschel et al. 1998). The inhibition of NF-κB and induction of apoptosis are enhanced by LPS (Ruckdeschel et al. 2001).

Fas-mediated apoptosis

Infection of human alveolar macrophages with *M. tuberculosis* causes apoptosis (Keane et al. 1997). Increased expression of FasL has been shown in macrophages within multibacillary leprosy and tuberculosis granulomas (Mustafa et al. 2001). Fas is a member of the TNF receptor family, which plays an important role in main-

taining lymphocyte homeostasis, and activation of Fas in the target cells by FasL is a key mechanism of $CD8^+$ CTL and Th1-mediated killing of target cells. The apoptosis can be rescued by TNF-α, IL-1β, or LPS (Mangan et al. 1991; Mustafa et al. 2001). However, it has also been shown that virulent strains of *M. tuberculosis* induce less macrophage apoptosis than attenuated strains; it was demonstrated that *M. tuberculosis* may evade apoptosis of macrophages through inhibition of TNF-α, and by stimulating release of IL-10 and soluble TNFR2 (Balcewicz-Sablinska et al. 1998).

Survival of *H. pylori* and the manifestation of peptic gastrointestinal diseases has been attributed to the *cag* pathogenicity island (PAI). Products of the *cag* PAI have been linked to the induction of apoptosis in epithelial cells (Wang et al. 2001; Jones et al. 2002). Mice deficient in Fas signaling have reduced epithelial cell apoptosis, impaired Th1 responses, and enhanced disease following *H. pylori* infection (Jones et al. 2002). Furthermore, antibodies to Fas or a caspase-8 inhibitor block the induction of apoptosis by *H. pylori*, whereas inhibition of FasL cleavage with a metalloprotease inhibitor increases apoptosis and this has been linked to products of the *cag* PAI (Wang et al. 2001). Persistent infection with strains expressing the *cag* PAI may be facilitated through negative selection of T cells encountering *H. pylori* antigens. *H. pylori* also induces apoptosis of macrophages and this has been linked to NF-κB-dependent induction of arginase (Gobert et al. 2002).

MODULATION OF DC MATURATION

Dendritic cells are considered to be the primary APCs for driving the differentiation of naïve T cells into distinct T-cell subtypes; therefore they play a key role in establishing immunological memory and in directing different arms of the T-cell response (Guermonprez et al. 2002). Immature DCs (iDC) are found in all lymphoid and many nonlymphoid organs, including mucosal tissues, where they exert a sentinel function, with high phagocytic activity. These iDCs endocytose antigens through a variety of receptors and have high capacity to process antigen for presentation by MHC molecules. Interaction with pathogens, including bacteria or their products, causes maturation of the DCs and migration to the T-cell areas of secondary lymphoid organs. The matured DCs have enhanced surface expression of MHCII costimulatory molecules, CD80 and CD86, and are highly efficient at presenting the processed MHC-bound peptides to T cells.

Infection of DCs with many bacterial species, including *L. monocytogenes*, *Salmonella* spp., *M. tuberculosis*, *M. bovis* BCG, *Treponema pallidum*, *Lactobacillus casei*, *B. pertussis*, *E. coli*, *S. aureus*, *Streptococcus gordonii*, *Mycoplasma catarrhalis*, and *C. trachomatis*, has been shown to activate DC maturation (Reis e Sousa et al. 1999). Maturation with most of these bacteria was associated with enhanced IL-12 secretion. In certain cases the bacterial molecules responsible for DC activation have been identified and many of these bind to TLRs and other PRRs. CpG motifs in bacterial DNA bind to TLR-9, flagellin from *L. monocytogenes* and *S. typhimurium* binds to TLR-5, LPS from gram-negative bacteria binds to CD14 and transduces signals through TLR-4, whereas peptidoglycan and lipoteichoic acid of gram-positive bacteria signal through TLR-2 (Ozinsky et al. 2000; Michelsen et al. 2001; Janeway and Medzhitov 2002). TLR-2 also recognizes lipoproteins derived from *M. tuberculosis*, *B. burgdorferi*, *T. pallidium*, and *Mycoplasma fermantes*, LAM from mycobacteria, glycolipid from *Treponema* spp., and LPS from *Leptospira* and *Porphyromonas* spp. (Akira et al. 2001).

Activation of DCs by different pathogen-derived molecules can influence the differentiation of naïve $CD4^+$ T cells into distinct T-cell subtypes, including Th1, Th2, or Tr cells (Figure 3). Binding of microbial molecules to TLRs activates a signaling pathway through NF-κB and MAP kinases, leading to activation of genes coding for inflammatory cytokines, including IL-12. CpG, LPS alone or with PT, can stimulate IL-12 production and activate iDCs into DC1 cells that drive the differentiation of naïve T cells into Th1 cells (Ausiello et al. 2002; de Jong et al. 2002). Stimulation of iDCs with CT or LT activates DC2 cells, which drive the differentiation of Th2 cells (Gagliardi et al. 2000). Finally, CT and *B. pertussis* FHA have been shown to activate DCs into a phenotype, termed DCr, which drives the induction of type 1 Tr cells (Lavelle et al. 2003; McGuirk and Mills 2002).

The induction of Th1 cells in response to infection with intracellular bacteria or the induction of Th2 cells by bacterial toxins or extracellular bacteria is central to the host antibacterial immunological defense mechanism. However, diverting the T-cell response to another nonprotective arm, such as Th2 or Tr1 responses during infection with intracellular bacteria, may be a strategy evolved by the bacteria to subvert protective immunity (see below under Modulation of cellular immunity). Alternately inhibition of maturation of the DCs by bacteria or their products can suppress the development of adaptive immunity to the pathogen. *L. casei* induces IL-12 production and maturation of DCs, whereas *L. reuteri* reduces *L. casei*-induced expression of IL-12 and CD86 (a cell surface costimulatory molecule) (Christensen et al. 2002), and induces a DC phenotype that may favor the induction of Th2 or Tr cells. Stimulation of murine DCs with FHA from *B. pertussis*, as well as activating DCs that drive the induction of Tr1 cells, inhibits the iDCs from maturing into DC1 cells, an effect mediated in part through the induction of IL-10 production (McGuirk et al. 2002).

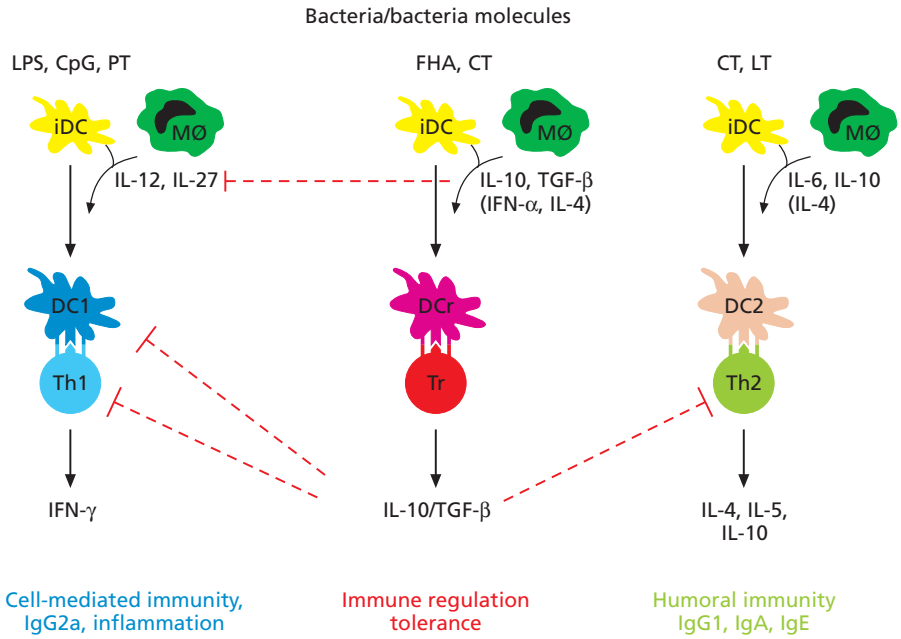

Figure 3 *Th cell subtypes in immunity to bacteria. Conserved bacterial structures interact with pathogen recognition receptors (PRRs) and activate maturation of the immature DCs (iDCs) into DC1, DC2, and DCr, which drive the differentiation of naive T-helper cells into Th1, Th2, or Tr cells respectively. Induction of regulatory cytokines by macrophages (Mϕs) and DCs in response to conserved bacterial molecules or virulence factors also plays a critical role in the selective development of distinct Th cell subtypes. Protective Th1 or Th2 cells are suppressed either directly or at the level of the antigen-presenting cells, through inhibitory cytokines, IL-10 and TGF-β, secreted by Tr cells. See text for abbreviations.*

MODULATION OF ANTIGEN PROCESSING AND PRESENTATION

Following bacterial uptake, antigens from the bacteria are processed by APCs and degraded peptides are presented in association with MHC molecules to T cells. $CD4^+$ T cells recognize processed antigens in association with MHCII molecules, which have been processed by an exogenous route of antigen processing. In contrast, antigens that are synthesized in host cells or escape from endosomes into the cytoplasm can enter the endogenous route of antigen processing for presentation by MHCI molecules to $CD8^+$ T cells. Finally, glycolipid antigens from bacterial cell walls can be presented by nonpolymorphic class I-like CD1 molecules to $CD8^+$ T cells or $CD4^-CD8^-$ NKT cells. Interference with the intracellular pathways that lead to the production of processed peptides or with the expression of MHC molecules on the surface of the APCs is a common strategy adopted by bacteria to subvert adaptive immune responses (Figure 4).

Interference with MHCII processing

Professional APCs, including DCs and macrophages, take up bacteria or their secreted soluble antigens by phagocytosis, macropinocytosis, or receptor-mediated endocytosis. The last occurs through interaction between antibody-coated, or antibody- and complement-coated, bacteria and Fc or complement receptors, or through direct binding of bacterial virulence factors to host cell surface ligands expressed on APCs and exploited by the bacteria for their uptake. Once inside an endosome the bacteria are transferred to late endosomes where they are degraded by lysosomal enzymes. Processed bacterial peptides associate with MHCII molecules after degradation of the invariant chain. Newly synthesized MHCII molecules with associated invariant chain are transported to the endocytic pathway, where an invariant chain-derived peptide class II-associated invariant chain peptide (CLIP) occupies the peptide-binding site in the class II molecule. In the class II-loading compartment CLIP is removed by interaction with HLA-DM and the bacterially-derived peptide is loaded. The stable MHCII-exogenous peptide complex is released to the cell surface where it interacts with the T cell receptor (TCR) of a $CD4^+$ T cell specific for that peptide.

The VacA toxin produced by *H. pylori* interferes with endocytosis in a process that requires Rab7 (Papini et al. 1997) and inhibits antigen processing by interfering with late endocytic membrane trafficking by APCs (Molinari et al. 1998). By lowering the amount of T-cell epitopes generated in the antigen-processing compartments, the toxin is capable of suppressing T-cell activation induced by APCs. Other pathogens have targeted the function of the class II-loading compartment. Patients with Chédiak–Higashai syndrome have a defect in a lyso-

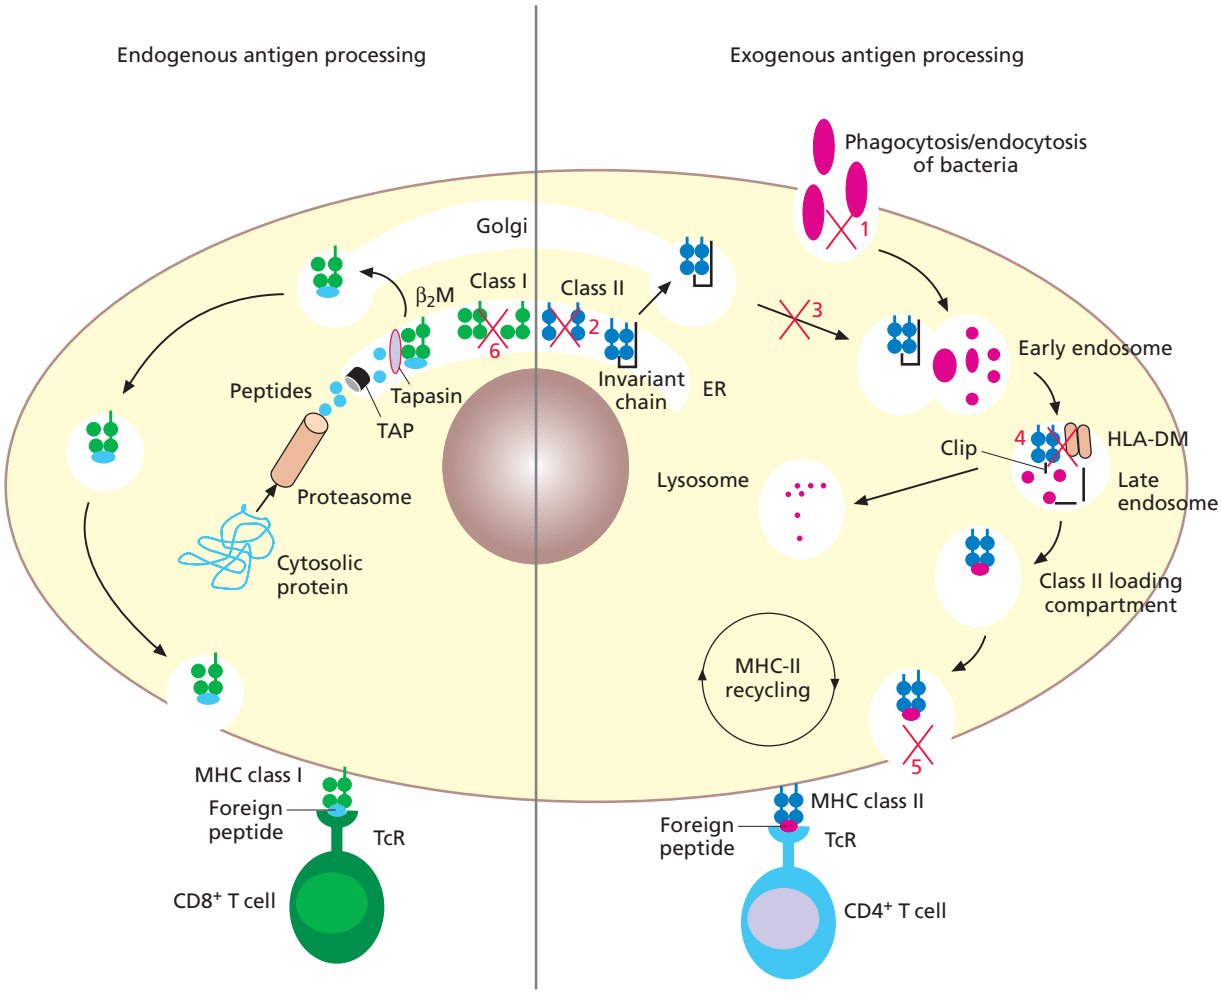

Figure 4 *Evasion of antigen processing and presentation. Exogenous antigens, including whole bacteria or bacterial proteins, are taken up by phagocytosis, endocytosis, or pinocytosis, and then degraded by proteolytic enzymes. In the endosome the processed antigen fragments or peptides associate with newly synthesized MHC class II molecules after removal of the invariant chain and the CLIP peptide by HLA-DM. The loaded MHCII molecule is exocytosed and presents the foreign peptide to CD4+ T cells on the surface of the APCs. Endogenous antigens that are synthesized in the host cells, or are released from endosomes into the cytosol, are processed by the proteasomes and TAP, before being loaded onto newly synthesized MHCI molecules in the endoplasmic reticulum. The loaded MHCI–peptide complex is exported to the cells surface, where it activates CD8+ cytoxic T lymphocytes. Bacteria can interfere with class II or I antigen processing and presentation by inhibiting: (1) phagocytosis/endocytosis, (2) class II biosynthesis, (3) export of class II molecules from the Golgi body to endosomes, (4) class II peptide loading, 5) export of the MHCII–peptide complex, or (6) class I biosynthesis. See text for abbreviations.*

somal-trafficking regulator and have enlarged lysosomes; B cells from these patients have altered peptide repertoires and delayed antigen presentation to T cells (Faigle et al. 1998). Enhanced interaction of human leukocyte antigen (HLA)-DR and HLA-DM, and more efficient removal of the CLIP peptide, may explain alterations in the dynamics of peptide loading observed in Chédiak–Higashai syndrome and in cells infected with *C. burnetii*, the rickettsial organism that causes Q fever (Lem et al. 1999).

Intracellular survival of *S. typhimurium* is facilitated by the *phoP* virulence locus, which controls the synthesis of many *Salmonella* proteins required for survival. The products of this locus also appear to affect antigen processing. Macrophages process model antigens expressed by *Salmonella* spp. more efficiently in *phoP-null* than wild-type bacteria (Wick et al. 1995). Furthermore, antigens in bacteria constitutively expressing PhoP are processed less efficiently by macrophages than wild-type bacteria. The *Salmonella phoP* virulence locus has also been found to be responsible for inhibiting antigen presentation in DCs. Although *S. typhimurium* expressing an ovalbumin (OVA) peptide induces maturation of the DCs, the *Salmonella phoP* virulence locus interfered with presentation of the OVA peptide to an OVA-specific T-cell hybridoma (Svensson et al. 2000).

Hemolytic strains of *L. monocytogenes* inhibit MHCII-restricted presentation of antigens to T cells. It has been suggested that listeriolysin, the hemolysin secreted by *L. monocytogenes*, inhibits antigen proces-

sing (Cluff et al. 1990). It was later reported that listeriolysin inhibits presentation of native antigens, but not peptides, to T cells; it was suggested that the defect was not caused by inhibition of antigen processing, but may result from irreversible inactivation of T cells that recognize antigen on listeriolysin-treated APCs (Darji et al. 1997).

Antigen processing can be inhibited by the ADP-ribosyltransferase activity of AB toxins; *E. coli*: heat-labile enterotoxin (LT) and cholera toxin (CT), but not the LT B subunit, CT B subunit, or nontoxic LT mutant LT-E112D, suppress intracellular antigen processing in APCs (Matousek et al. 1998). CT and LT inhibited processing of hen egg lysozyme (HEL) expressed in *E. coli* as a HEL fusion protein (containing the HEL 48–61 epitope), but not presentation of pre-existing peptide MHCII complexes to T-cell hybridomas (Matousek et al. 1996, 1998). In contrast, the B subunits of CT or LT or a mutant of LT with reduced enzyme activity do not affect antigen processing, but do enhance antigen presentation (Matousek et al. 1996, 1998). This is consistent with the demonstration that pre-treatment of APCs with wild-type LT or partial inactive mutant LTR72, but not the nontoxic mutant LTK63, suppresses IFN-γ production by a Th1 clone (Ryan et al. 2000). However, APC treatment with LT or LTR72 enhances IL-5 production by a Th2 clone (Ryan et al. 2000).

Yersinia YopH can inhibit activation of B cells by interfering with B-cell antigen-receptor adhesion. Following coincubation with *Yersinia*, B cells are unable to upregulate surface expression of B7-2 (CD86) in response to antigen stimulation (Yao et al. 1999). Downregulation of B7 expression on APCs may also contribute to defective antigen-induced T-cell activation after infection of mice with *M. tuberculosis* (Saha et al. 1994). Delayed-type hypersensitivity responses to crude soluble mycobacterial antigen were suppressed in infected susceptible BALB/c mice, but not in resistant C3H/HeJ mice. The defect appeared to lie in the inability of infected macrophages to provide a costimulatory signal for T cells (Saha et al. 1994).

Modulation of MHCII biosynthesis, intracellular trafficking, and cell surface expression

Different strains of mycobacteria have been shown to have varying abilities to inhibit antigen presentation to T cells by downregulating MHCI and MHCII expression on APCs, and the virulence of the organism has been related to these properties (Weiss et al. 2001). Diminished IFN-γ-induced cell-surface expression of HLA-DR on cells infected with *M. tuberculosis* results from defective transport and processing of class II molecules through the endosomal/lysosomal system (Hmama et al. 1998). Infection of macrophages with *M. bovis* has also been shown to downregulate IFN-γ-induced expression of class II transactivator (CIITA) mRNA, leading to inhibition of induction of MHCII molecules (Wojciechowski et al. 1999). Infection of macrophages with *M. avium* has been shown to arrest phagosome maturation, which limits the intersection of mycobacteria-containing phagosomes with the intracellular trafficking pathways of antigen presentation and results in sequestration of intracellular pools of MHCII and H-2 M molecules (Ullrich et al. 2000).

Phagocytosis of *S. aureus*, *E. coli*, *P. aeruginosa*, or *Salmonella enteritidis* by human monocytes reduces their ability to present an unrelated antigen, purified protein derivative (PPD) to T cells (Pryjma et al. 1994). Although antigen processing is not affected, the infected cells have reduced expression of MHC and accessory molecules, suggesting that the defect is caused by interference with antigen presentation. Phagocytosis of mycobacteria or *E. coli* by monocytes resulted in a failure to process and present antigens to MHCII-restricted T cells as a result of downregulation of MHCII expression, caused by a transient block in the transport of mature class II heterodimers to the surface of the APCs (De Lerma Barbaro et al. 1999). *Chlamydia* spp. can inhibit IFN-γ-induced MHCII expression on epithelial cells, but not IFN-γ-induced expression of the adhesion molecule ICAM-1 or IFN regulatory factor-1 (IRF-1), suggesting that it specifically targets signaling pathways required for MHCII expression (Zhong et al. 1999). The mechanism appears to involve diminished expression of IFN-γ-induced CIITA resulting from degradation of the transcriptional factor, upstream stimulatory factor-1 (USF-1), required for IFN-γ induction of CIITA.

Interference with MHC class I processing and presentation

Unlike viruses, where $CD8^+$ T cells play a major role in limiting infection by killing virally infected cells, MHCI-restricted T cells are induced only against certain intracellular bacteria. Extracellular bacteria do not enter the endogenous route of antigen processing and many intracellular bacteria can survive in intracellular locations distinct from class I processing sites. Therefore strategies for bacterial evasion of class I processing and presentation pathways are more limited. Nevertheless there are a number of reports that demonstrate that certain intracellular bacteria can inhibit expression of MHCI molecules or can bring about changes in the peptide repertoire bound to MHCI molecules.

Infection of murine macrophages with *L. monocytogenes* suppresses constitutive and IFN-γ-induced MHCI gene expression (Schuller et al. 1998). *Chlamydia* spp. can also suppress IFN-γ-induced MHCI expression in infected cells and the mechanism appears to involve degradation of USF-1 and RFX5, an essential down-

stream transcription factor required for constitutive and IFN-γ-induced MHCI expression (Zhong et al. 2000). *Chlamydia pneumonia* infection of monocytes down-regulates expression of MHCI molecules by inducing the production of IL-10 (Caspar-Bauguil et al. 2000). Thus *C. pneumonia* may suppress $CD8^+$ T-cell responses by inhibiting presentation of bacterial epitopes by MHCI molecules.

Expression of the nonclassic class I molecule, CD1, which presents mycobacterial glycolipids to unconventional T cells, is inhibited after infection of APCs with *M. tuberculosis* (Stenger et al. 1998). The loss of CD1 from the cell surface was associated with complete inhibition of antigen presentation to CD1-restricted T cells.

Invasion of HLA-B27-expressing HeLa cells by *S. typhimurium* enhances expression of IFN-γ-inducible proteasome genes, *LMP*, *MECL*, and *PA28*, and alters the peptide repertoire of HLA-B27 in the infected cell (Maksymowych et al. 1998). The altered peptide repertoire appeared to include peptides of host origin, suggesting that the infection may lead to the generation of autoreactive $CD8^+$ CTLs.

EVASION OF THE HUMORAL RESPONSE

Following activation of the adaptive immune response, B cells produce high concentrations of high-affinity pathogen-specific antibodies, which play a major role in protection against extracellular bacteria. Antibodies directed against adhesins and invasins limit colonization, whereas those directed against bacterial toxins prevent their binding to host target cells and thereby reduce the severity of disease. Murine IgG2a antibodies promote phagocytosis by opsonizing the bacteria and stimulating the complement components C3b and iC3b, which bind complement receptors and further promote phagocytosis. IgA antibodies, induced after bacterial infection of mucosal tissues, function to limit the infection at these sites. In an immune individual primed by a self-limiting infection or immunization, antibodies probably play the major role in conferring protective immunity. Therefore bacteria have evolved strategies to circumvent humoral immunity by evading both complement- and antibody-mediated immune responses (Figure 5).

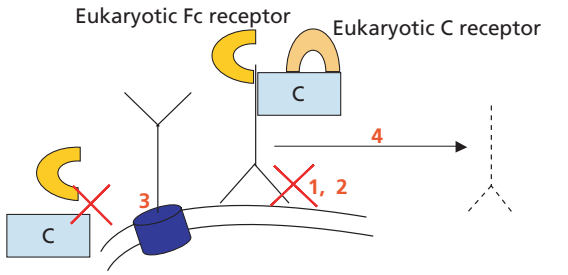

Figure 5 *Evasion of antibodies. Specific antibodies bind their cognate ligands on the bacterial surface, recruiting complement factors to the site. The antibodies and complement are recognized by Fc and C receptors on phagocytic cells, which mediate uptake into these cells. The complement cascade is also activated to form membrane attack complexes (MAC) and lyse the bacteria. Evasion of antibodies by bacteria can occur in a number of ways: (1) masking of the bacterial surface from antibody recognition, (2) avoidance of antibody recognition by antigenic and phase variation, (3) binding of antibodies by antibody-binding proteins, and (4) degradation and modification of antibodies.*

Antigenic variation and phase variation

Most bacteria can vary their surface composition to some extent (Henderson et al. 1999; Hallet 2001). The capacity to vary surface antigens can aid in evasion of complement-mediated killing and opsonophagocytosis, as new antigens are not recognized by existing antibodies and the classic pathway of complement does not become activated. Many of the complement-binding molecules of bacteria undergo phase and/or antigenic variation, giving rise to differences in the levels of serum resistance in different isolates and strains of the same bacterial species.

Antigenic variation of proteins occurs mainly by spontaneous point mutations in the genes encoding the protein antigen, such that the physical topography of the molecule is altered and antibodies directed against the original antigen do not recognize the altered one. Using phase variation, bacteria frequently and reversibly undergo altered expression of surface molecules resulting from genetic alterations in specific loci of their genomes. These two types of genetic alterations are particularly dominant in two classes of loci: (1) genes encoding surface structures such as LPS, flagella, and fimbriae, and (2) genes encoding virulence factors that modify host cell physiology or protect the bacteria from antimicrobial systems in the host. These surface structures not only affect bacterial virulence but are also key targets of the host immune system, resulting in selective pressure to generate polymorphism in genes coding for antigenic diversity. Varying expression and composition of these molecules allow bacteria not only to counteract the host immune defenses but also to colonize new ecological niches. These variations can be very extensive. In *S. enterica* there are more than 2000 separate serotypes based on differences in carbohydrate structures, such as LPS, and also flagella antigens (Fierer and Guiney 2001). There is enormous variation in the virulence and epidemiology of these serotypes.

CAPSULES

Phase variation can control gene expression in an 'on–off' manner. Genes for the biosynthesis of capsules in *Neisseria meningitidis* and *Haemophilus influenza* undergo this type of regulation (Gilsdorf 1998). The presence of a capsule may be beneficial in some circum-

stances, e.g. in the formation of biofilms, and a hindrance in others, e.g. for the motile stages of bacterial life. Bacteria growing in biofilms are highly resistant to the immune system of the host. Soluble factors and immune cells have limited access to bacteria in these circumstances as a result of the network of extracellular material surrounding the bacteria. Chronic bacterial infections, such as *P. aeruginosa* infections in the lungs of cystic fibrosis patients and *S. aureus* infections of prostheses, are difficult to treat because of the biofilm nature of growth of the bacteria. However, spread of the bacteria is enhanced when they are released from the biofilm capsule.

LPS AND LIPOOLIGOSACCHARIDE

Bacteria can alter surface molecule composition by controlling expression of genes for LPS and lipooligosaccharide (LOS) biosynthesis and modification (Lerouge and Vanderleyden 2002). LPS variations are mostly caused by differences in the polysaccharide side chains resulting from polymorphisms in the genes that encode the machinery to synthesize these polysaccharides (Liu et al. 1991). Furthermore, the regulation of lipid A modifications by *Salmonella* spp. renders these bacteria more resistant to antimicrobial peptides and renders the LPS less stimulatory for macrophages (Guo et al. 1997). LPS interacts with both antibodies and complement, and much of antibody response to *Salmonella* infection is directed against LPS O-antigens. LPS-specific antibodies play a major role in protecting against *Salmonella* infection and LPS variation allows *Salmonella* spp. to infect hosts that already have antibody directed against a different O-antigen serotype. Variation of LPS during infection may also be advantageous. Changes in *Salmonella* LPS structure result in changes in opsonin binding, in phagocytosis and killing by neutrophils, and in virulence (Jimenez-Lucho et al. 1987; Johnson et al. 1992). Other bacteria that alter their LPS composition include *H. pylori* and *L. pneumophila* (Appelmelk et al. 2000). During the course of an infection, antigens may vary or change with the host response and in *H. pylori* certain LPS structures mimic the eukaryotic Lewis antigens, allowing the bacteria to evade recognition and elimination. *C. jejuni*, *Neisseria gonorrhoeae*, and *H. influenzae* are all capable of altering their LOS structure (Gilsdorf 1998; Harvey et al. 2000; Linton et al. 2000). Acquisition of new LOS epitopes by *H. influenzae* is associated with increased resistance to complement-mediated serum and occurs rapidly among isolates (Kimura and Hansen 1986).

PROTEINS

Outer membrane proteins (OMP) frequently undergo phase and antigenic variation. *N. gonorrhoeae* strains may carry up to 12 phase-variable *opa* genes, encoding OMPs mediating bacterial adhesion and invasion. The expression of these functionally redundant genes is variable, thereby allowing the generation of antigen variants while maintaining and diversifying essential activities. The surface layer protein of *Campylobacter fetus* and OspC of *Borrelia* spp. also undergo antigenic variation (Dworkin and Blaser 1997). Pili and flagella are subject to variation, e.g. *N. gonorrhoea* has 18–19 pilin cassettes with which to make variable type IV pili. *Salmonella* flagella stimulate and activate macrophages and different flagella have varying potencies, suggesting that this flagellar phase variation may be a mechanism to downregulate inflammatory responses (Ciacci-Woolwine et al. 1998).

The *H. influenzae* IgA protease undergoes antigenic variation with over 30 serotypes and, in some cases, these variants result in changes in IgA protease specificity and its antibody inhibition pattern. (Lomholt et al. 1993). A global effect on gene expression can be achieved by variation in expression of a global regulator such as BvgAS of *Bordetella* spp. The acquisition or loss of unstable genetic elements (e.g. in *L. pneumophila*) or pathogenicity islands (e.g. SPI-1 and SPI-2 of *Salmonella* spp.) or pathogenicity plasmids (e.g. pYV plasmids of *Yersinia* spp.) in virulent bacteria can lead to significant changes in the protein composition of the bacterial membrane.

Antigenic variation contributes to the adaptive capacity of the bacterium for new environments and for survival. The ability to rapidly produce and modify specific structures on the cell surface is crucial in the establishment of infection, particularly with respect to the variety of biological niches within the host. Phase variation results in a more versatile and heterogeneous population that can cope better with a variety of different environments. It may result in better colonization as changes arise in structures mediating attachment and invasion of eukaryotic cells. It may lead to better evasion of host defenses as variation allows the bacteria to escape the neutralizing activities of antibodies and thus evade pre-existing host immunity.

Antibody-binding proteins

Several bacteria express immunoglobulin Fc-domain binding proteins, which are associated with the cell surface or released in soluble form from the surface. Binding of immunoglobulins via their Fc portion on the bacterial surface is thought to form a protective covering on the bacteria so that the bacteria are no longer recognized as foreign, and access of complement and specific antibodies to the bacteria is obstructed. Binding of IgG to Fc receptors on bacteria (e.g. SfbI on *Streptococcus pyogenes*) inhibits Fc-mediated phagocytosis by macrophages and antibody-dependent cell-mediated cytotoxicity (Medina et al. 1999). The best-known Ig-binding proteins are protein A of *Staphylococcus* spp. and protein

G of *Streptococcus* spp. (Kronvall 1973; Reis et al. 1984). One of the key events in the elimination of antigen or antigen–antibody complexes (immune complexes) is the covalent binding of C3b. This binding promotes uptake by phagocytic cells via C3 receptors. The two C3b-binding sites on IgG overlap the two regions that are bound by bacterial proteins such as protein A and protein G. Thus, these bacterial proteins directly interfere with C3b binding to the Fc region of IgG (Munoz et al. 1998). The surface-bound, M-protein family of *Streptococcus* spp. is made up of highly characterized, immunoglobulin-binding proteins and in most cases they bind only a single antibody class (Navarre and Schneewind 1999). There is also species specificity in the antibody binding. Binding of both IgG and IgA or IgG alone is found in all-invasive disease, group A streptococcus clinical isolates, whereas it is not so common in septicemia and noninvasive throat isolates (Raeder and Boyle 1995).

Human IgA is abundant in the secretions at mucosal surfaces such as those lining the lungs, gut, and genitourinary tract. These surfaces represent major potential sites of invasion and the immune protection offered by secretory IgA, as the predominant antibody at these sites, serves as a critical initial defense against pathogens. IgA recognizes and binds bacteria and triggers their elimination by interaction of its Fc domain with an Fcα receptor (FcαRI) expressed on neutrophils, eosinophils and macrophages. This interaction stimulates phagocytosis, superoxide generation and release of enzymes and inflammatory mediators. Two *S. pyogenes* IgA Fc-binding proteins, Arp4 and Sir22, both of the M-protein family, are important for virulence (Stenberg et al. 1994; Thern et al. 1998). Arp4 has been shown to inhibit a respiratory burst triggered by the binding of IgA-Fc to FcαRI on neutrophils. B protein of group B *Streptococcus* spp. also binds IgA (Jerlstrom et al. 1991). These three proteins all bind the Cα2-Cα3 interdomain of the IgA Fc domain. This domain is responsible for binding FcαRI and the streptococcal IgA-binding proteins interfere with this interaction (Pleass et al. 2001).

Antibody degradation and modification

Bacteria can degrade immunoglobulins to inactivate them. The degrading proteins are enzymes of broad proteolytic activity, which may also degrade complement and other host factors. IgG is degraded by the *P. gingivalis* PrtH protease, which in addition degrades the complement component C3 (Fletcher et al. 1995). Similar cell-associated proteases are present in *Lactobacillus* and *Streptococcus* spp. (Siezen 1999). IgA1 is degraded by the three leading causes of bacterial meningitis, *H. influenzae*, *N. meningitidis*, and *S. pneumoniae*, important urogenital pathogens, and some members of the oropharyngeal flora. These proteases are important for the ability of bacteria to colonize mucosal membranes in the presence of secretory IgA antibodies and result in a local functional IgA deficiency.

IgA can be inactivated by modification of its immunoglobulin structure. *Streptococcus* and *Veillonella* spp. can remove terminally positioned sialic acid from IgA1. This may have an immune evasion function, because sialic acid protects glycoproteins, including immunoglobulins, from proteolytic enzymes. Deglycosylation of antibodies increases their sensitivity to proteolytic degradation and inhibits the Fc-mediated effector functions that mediate antigen disposal.

EVASION OF COMPLEMENT

The complement system plays a major role in resistance against microbial infections participating in both specific and nonspecific immunity (Rautemaa and Meri 1999). The complement activation pathways comprise a complex set of serum proteins that are activated by antigen–antibody complexes (classic pathway), certain carbohydrates (lectin pathway), or a variety of pathogen surface molecules (alternate pathway). Activation of complement has a number of consequences. Some complement activation products such as C3b, iC3b, C4b, and C1q are opsonins, inducing recognition and phagocytosis of the bacteria by macrophages and polymorphonuclear granulocytes. C3a, C4a, and C5a increase vascular permeability and induce inflammation. The chemotactic C5a also attracts leukocytes to the site of infection and activates them. Membrane attack complexes (MAC), composed of multiple complement factors, form on the surfaces of gram-negative bacteria and cause the collapse of membrane potential, leading to lytic cell death. Microbial activation of the complement system eventually leads to phagocytosis of the target and/or lysis of the bacteria by MACs. Given the dramatic effects of complement activation in the host, the complement system is tightly controlled to protect host cells from complement attack. Both soluble inhibitors, such as factor H, and cell membrane glycoproteins, such as protectin, are critical for regulating complement activation. Protectin regulates MAC insertion into membranes. Factor H inhibits the alternate pathway and C4bp inhibits the classic pathway, by both inhibiting interactions between the complement components and enhancing complement component degradation. Pathogenic bacteria have evolved strategies to evade and inhibit the complement system in order to resist opsonophagocytosis and/or complement-mediated cytolytic damage (Figure 6) (Rautemaa and Meri 1999; Wurzner 1999).

Masking the bacterial surface

Pathogens can mask their membrane surfaces to avoid recognition by complement. Prevention of access of

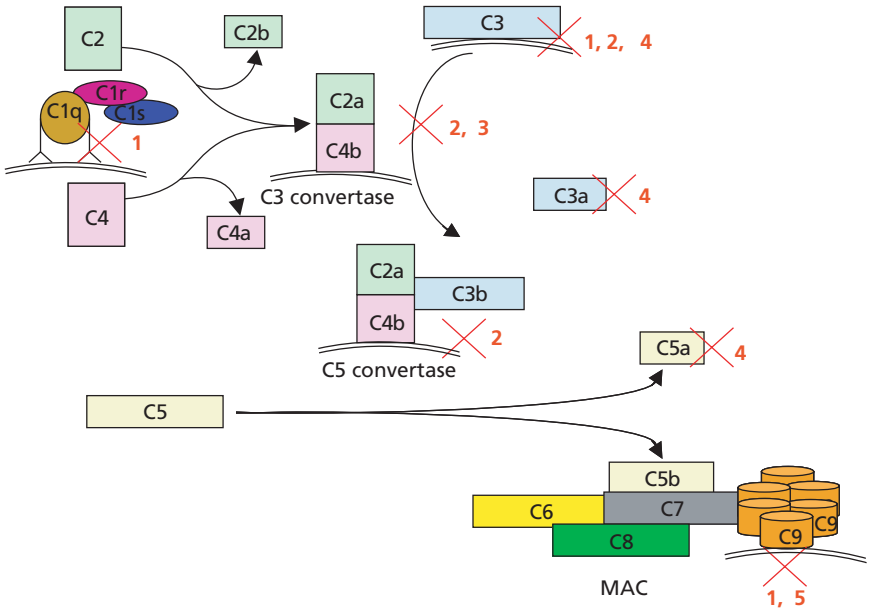

Figure 6 *Evasion of complement. In the classic complement cascade antibodies bound to the surface of bacteria recruit C1q, C1r, and C1s. This binding stimulates the cleavage of C2 and C4, releasing C2b and C4a. C2a and C4b associate to form the C3 convertase, which induces cleavage of C3 to C3a and C3b, thus forming a C5 convertase. C1q, C3b, and C4b are opsonins inducing recognition and phagocytosis of the bacteria by macrophages and polymorphonuclear granulocytes, whereas C4a and C5a are anaphylatoxins increasing vascular permeability and inducing inflammation. C5b and the chemotactic C5a are formed from C5, and C5b together with C6, C7, and C8 recruits the assembly of C9 components to form a lytic membrane attack complex (MAC). C3 and C5 convertases and MACs are also generated by the alternate complement pathway. Bacteria use a number of mechanisms to evade complement activation and killing: (1) masking of the bacterial surface, (2) shedding of complement complexes from the bacterial surface, (3) binding of complement inhibition factor H, (4) cleavage of complement components, and (5) inhibition of MAC insertion.*

complement to the cell membrane can by achieved by expression of polysaccharide capsules and/or long and dense LPS by gram-negative bacteria. These structures hinder access of both the initial complement factors and the lytic MACs. The insertion of MACs into the bacterial membrane is inhibited in gram-positive bacteria as a result of the presence of the surrounding peptidoglycan. *S. aureus* capsule expression leads to reduced C3 deposition on the bacterial surface, in turn leading to decreased phagocytic killing in vitro and increased lethality in vivo (Thakker et al. 1998; Cunnion et al. 2001). *S. pneumoniae* capsule expression also leads to decreased C3 deposition and the *H. influenzae* capsule is required for serum resistance and virulence of invasive strains (Brown et al. 1983; Noel et al. 1996). Group B meningococci and group B streptococci express capsular polysaccharides that are rich in sialic acid, which is relatively nonimmunogenic and prevents complement activation (Edwards et al. 1982). LPS composition influences recognition by complement, as in the case of some *Salmonella* spp. which possess LPS with long *O*-polysaccharide side chains that sterically hinder access of complement components such as C1q and MACs to the bacterial membrane and bacterial OMPs (Joiner et al. 1982a, 1982b; Liang-Takasaki et al. 1983). The LPS structure of *Klebsiella pneumoniae*, *C. burnetti*, and *B. abortus* also renders these bacteria more resistant to complement (Vishwanath et al. 1988; Merino et al. 1992; Eisenschenk et al. 1999).

Shedding

Bacterial pathogens can shed strong complement-activating surface molecules and immune complexes from their cell surfaces. Shedding prevents the accumulation of complement factors on the bacterial membrane and also diverts antibodies away from the bacterial surface. *S. aureus* sheds up to 30 percent of the C3 deposited on its surface (Cunnion et al. 2001) and *E. coli* and *S. minnesota* also shed complement factors and/or assembled complement complexes from their cell surfaces (Joiner et al. 1982a; Joiner 1988). Shedding of complement complexes from the surface of *S. pneumoniae* involves the action of the host complement inhibitory factor, protein H (Berge et al. 1997).

Cleavage of complement

Just as bacteria degrade antibodies to inactivate them, bacteria also degrade complement factors to inhibit activation of the complement pathway. *P. aeruginosa* cleaves complement components by extracellular secreted proteases, as do *H. pylori* and *P. gingivalis* (Hong and

Ghebrehiwet 1992; Schenkein et al. 1995; Rokita et al. 1998). *P. aeruginosa* elastase inactivates the anaphylatoxins C3a and C5a, resulting in a reduced inflammatory response. The PrtH protease of *P. gingivalis* is an important virulence factor for the bacterium because it degrades C3, resulting in a reduction of C3b and C3bi on the bacterial surface and inhibition of phagocytosis by neutrophils. *S. pneumonia* degrades C3 by a cell-associated activity that leads to inactivation of C3 and release of C3 from the bacterial surface whereas group A *S. pyogenes* possesses a cell wall-anchored C5a peptidase to inactivate C5a (Wexler et al. 1985; Angel et al. 1994).

Binding complement inhibition proteins

To avoid elimination by complement, microbes can exploit complement regulatory factors of the host. Some bacteria bind proteins, such as factor H or C4bp, that negatively regulate complement activation. The binding of factor H or C4bp confers serum resistance to bacteria and prevents their phagocytosis. Many of these binding molecules undergo phase and/or antigenic variation, giving rise to differences in the levels of serum resistance in different isolates and strains of the same bacterial species. Serum resistance is a major determinant of *N. gonorrhoeae* virulence, because serum-sensitive gonococci predominantly result in symptomatic local inflammation, whereas serum-resistant strains are associated with disseminated infection. The source of complement resistance in these bacteria is sialyation of low-molecular-weight LOS (Ram et al. 1998). Sialic acid-containing structures enhance the interaction between C3b and factor H. Binding of factor H to sialyated LOS leads to rapid conversion of surface-bound C3 to iC3b and to elimination of complement activation components from the cell surface. OMPs are also involved in binding factor H with similar consequences, e.g. *N. gonorrhoeae* Por1A which also binds C4bp and the expression of which correlates with serum resistance and disseminated gonococcal disease (Ram et al. 1998, 2001). Other factor H- and/or C4bp-binding proteins include the majority of the streptococcal M protein family, a family of more than 80 antigenically distinct proteins, most of which have antiphagocytic activity (Horstmann et al. 1988; Johnsson et al. 1996). The M-protein–C4bp interaction is important for serum resistance in these bacteria. In addition, several M-proteins bind immunoglobulins IgG and/or IgA through the constant Fc portion.

Inhibition of MAC insertion

Several gram-negative bacteria can interfere with the assembly of terminal MACs and thereby prevent lethal outer cell membrane damage. The related OMPs, Rck of *S. typhimurium* and Ail of *Y. enterocolitica*, cause a failure in the formation of fully polymerized tubular MACs (Heffernan et al. 1994). The TraT lipoproteins of *Salmonella* spp. and *E. coli* increase resistance to complement killing by interference with the generation of complement factors, and the correct assembly and membrane insertion of MACs (Pramoonjago et al. 1992). The Sic protein of *S. pyogenes* is important for mouse mucosal colonization and inhibits the normal cytolytic effect of MACs (Akesson et al. 1996).

MODULATION OF CELLULAR IMMUNITY

Inhibition of T-cell activation and proliferation

T cells recognize antigens through engagement of the TCR with processed antigenic peptide associated with an MHC molecule expressed on the surface of an APC. However, activation of the T cell is dependent on a second signal provided by interaction of CD28 on the T-cell surface with costimulatory molecules CD80 or CD86, expressed on the surface of activated APCs. In the absence of the second signal, the T cells become anergic and are no longer able to divide or respond to antigen. Engagement of CD3 and CD28 results in redistribution of lipid rafts to the interface between the T cells and APCs. Clustering of TCRs activates the T cell by bringing together tyrosine kinases and permitting their phosphorylation, which initiates a signaling cascade through the CD3 complex and leads to activation of genes required for proliferation and cytokine secretion. Proliferation of T cells with APCs or unpurified PBMCs in vitro, in response to foreign antigen or mitogens, which crosslink surface receptors on the T cells, is often used as a measure of T-cell activation. Alternately, the cytokine secretion pattern is used as an index of activation (or suppression) of distinct T-cell subtypes. Although IL-2 has been used as a marker of Th1 cells, it is now evident that this cytokine can be secreted by precursor T cells as well as by activated Th1 cells. IFN-γ production, without IL-4, IL-5, or IL-10 is a useful marker of Th1 responses, whereas IL-4 and IL-5 without IFN-γ can be used to define Th2 cells. The recently described Tr cells can also be discriminated from Th1 or Th2 cells on the basis of anti-inflammatory cytokines: IL-10 with or without TGF-β but no IL-4 or IFN-γ for Tr1 cells, and TGF-β, with or without IL-10 but no IL-4 or IFN-γ for Th3 cells.

As T-cell activation is an essential step in cellular and humoral immune responses to infectious pathogens, many bacteria have evolved strategies to evade adaptive immunity by suppressing T-cell responses. In a limited number of cases the bacterial molecule and its host cell target have been identified, but most studies on

suppressed T-cell responses during bacterial infection have not established the mechanism. Interference with any aspect of antigen uptake processing or presentation by the APCs or signaling in the T cell can inhibit T-cell activation. Furthermore, as activation of distinct T-cell subtypes is regulated by the reciprocal cell populations, factors that strongly promote the induction of one subtype may inhibit the activation of another. Consequently, suppression of T-cell responses or specific T-cell subtypes may reflect subversion of many different aspects of innate as well as adaptive immunity dealt with in other parts in this chapter.

Infection of mice with an attenuated *aroA* strain of *S. typhimurium* results in profound immunosuppression, with inhibition of T- and B-cell proliferation to foreign antigen (al-Ramadi et al. 1991a) and of the T cell's production of IL-2 in response to concanavalin A (Con A) (al-Ramadi et al. 1991b). *H. pylori* suppresses in vitro proliferative responses of human PBMCs to mitogens and antigens and a soluble cytoplasmic fraction of *H. pylori* mediates the suppression by acting on monocytes and directly on the T cells (Knipp et al. 1994). Nitric oxide (NO) was later identified as a soluble macrophage-derived factor capable of mediating *Salmonella*-induced immunosuppression (Gregory et al. 1993; MacFarlane et al. 1999). Treatment of mice with the NO inhibitor, aminoguanidine hemisulfate, blocks the suppressive effect of *Salmonella* infection on T- and B-cell responses, but it also blocks influx of neutrophils and macrophages into the spleen, which was associated with enhanced bacterial load and higher mortality of the mice (MacFarlane et al. 1999), suggesting that NO is involved in host defense as well as immunosuppression. Suppression of T-cell responses by *S. typhimurium* was also found to be mediated by soluble factors released by monocytes/macrophages and was reversed by the addition of IL-4 (al-Ramadi et al. 1991b).

In a limited number of bacterial infections where suppression of T-cell responses has been observed, the immunomodulatory molecules involved have been identified. *Yersinia pseudotuberculosis* can inhibit T- and B-cell activation by interference with T- and B-cell antigen-receptor activation; the effect is mediated by YopH, which has tyrosine phosphatase activity (Yao et al. 1999). Patients with lepromatous leprosy are highly immunosuppressed; their T cells do not respond to *Mycobacterium leprae* antigens and macrophages and $CD8^+$ T cells have been implicated in the suppression (Mehra et al. 1984; Salgame et al. 1984). The *M. leprae* antigen LAM-B, can suppress proliferative responses of PBMCs from lepromatous leprosy patients, tuberculoid leprosy patients, and normal individuals (Kaplan et al. 1987). Lipoglycans from *M. leprae* have also been shown to induce immune suppression in mice, including inhibition of delayed type hypersensitivity (DTH) responses and proliferation of lymph node cells to mitogens (Moura and Mariano 1997).

The OspA protein of *B. burgdorferi* inhibits proliferative responses of human PBMCs to phyohemagglutinin and Con A (Chiao et al. 2000). *B. burgdorferi* infection of disease-susceptible (C3H/HeJ) and disease-resistant (BALB/c) mice results in impaired proliferation of IL-2 and IL-4 production to mitogens (de Souza et al. 1993). More recently it has been suggested that Th1 responses are suppressed whereas Th2 responses are enhanced; *B. burgdorferi* transmission by *Ixodes scapularis* suppressed IL-2 and IFN-γ and enhanced IL-4 production in mice (Zeidner et al. 1997). Similarly, the inhibitory effect of *E. coli* LT on T-cell responses was shown to be specific for Th1 cells and was mediated by the effect of ADP-ribosyltransferase enzyme activity on APCs as well as on T cells (Ryan et al. 2000). Furthermore, it has been reported that *E. coli* LT-treated epithelial cells release soluble factors, probably prostaglandins, that inhibit proliferation of a T-cell hybridoma in vitro (Lopes et al. 2000).

Upsetting Th1/Th2 balance

The demonstration that T cells could be discriminated on the basis of cytokine secretion and function had a considerable impact on our understanding of immunity to infectious diseases. Following the discovery of Th1 and Th2 subtypes of $CD4^+$ T cells in the 1980s, a dogma emerged which stated that Th1 cells secreted IFN-γ and TNF-β and mediated cellular immunity against intracellular pathogens, including viruses and intracellular bacteria, whereas Th2 cells were the true helper cells and mediated humoral immunity against extracellular bacteria and parasites. Furthermore, as Th1 and Th2 responses are crossregulated through IL-4/IL-10 and IFN-γ secreted by the reciprocal subtypes, any upset in the balance of Th1 or Th2 cells could prolong the course of different infections and this could be used as a strategy for pathogens to prolong their survival in the host (see Figure 3, p. 13). To a certain extent that still holds; however, it is now full recognized that Th1 cells also provide help for B-cell production of antibody subclasses involved in virus neutralization, opsonization of extracellular bacteria, and complement fixation. Furthermore, other populations of $CD4^+$ T cells with suppressive function, termed 'Tr cells' may also inhibit protective Th1 and possibly Th2 responses to infectious agents.

In the field of bacterial immunity, *M. leprae* provides one of the best examples of the influence of Th1/Th2 responses on the outcome of infection. In patients with lepromatous leprosy, cellular immune responses to many antigens are profoundly depressed and T cells in these patients are also anergized to unrelated antigens. These patients make potent antibody responses to the bacteria but are not protected. In contrast, patients with tuberculoid leprosy have potent cellular immune responses and

their macrophages can kill the bacteria. The important distinction between the two diseases states is that the patients with lepromatous leprosy mount Th2 responses, which are not protective, whereas in the tuberculoid leprosy patients Th1 cells are dominant and IFN-γ secreted by these cells activates infected macrophages to kill the bacteria (Sieling and Modlin 1994).

A failure of Th1-cell induction or function has also been shown to result in increased susceptibility to other bacterial infections. Development of *B. burgdorferi* infection after transmission by *I. scapularis*, in disease-susceptible C3H/HeJ mice, is associated with the development of Th2 responses, but not in disease-resistant BALB/c mice (Zeidner et al. 1997). Th1 cells have been implicated in clearance of primary infection and preventing reinfection with *B. pertussis* and mice develop disseminating disease in the absence of functional IFN-γ (Mahon et al. 1997). However, Th1 responses are suppressed in the lungs and draining lymph nodes during acute infection (McGuirk et al. 1998), and this appears to result from a variety of immune subversion strategies by the bacteria, including the induction of *B. pertussis*-specific Tr cells (McGuirk et al. 2002).

Pathogen-specific IL-10/TGF-β secreting Tr cells

$CD4^+$ T cells that constitutively express the IL-2α receptor (CD25) in vivo have been shown to have immunosuppressive properties and to be capable of preventing autoimmune diseases mediated by Th1 cells. Suppressor $CD4^+$ T cells that secrete TGF-β were termed 'Th3 cells' (Chen et al. 1994) and suppressor T-cell clones that secreted high levels of IL-10 and IL-5, but not IFN-γ or IL-4, were termed 'Tr1 cells' (Groux et al. 1997). It was suggested that the primary function of these Tr cells is to maintain immunological homeostasis and tolerance to selfantigens. However, recent evidence suggests that these cells can also be generated against foreign antigen on infectious pathogens.

The first report on Tr cell clones specific for a bacterial antigen were murine Tr1 cells specific for the *B. pertussis* antigens FHA and pertactin from the lungs of *B. pertussis*-infected mice (McGuirk et al. 2002). Human Tr1 or Th3 clones have also been generated against the filarial parasite *Onchocerca volvulus* (Doetze et al. 2000) and the hepatitis C virus core protein (MacDonald et al. 2002). Functional studies on the *B. pertussis*-specific Tr1 clones demonstrated that they were capable of suppressing IFN-γ production by Th1 responses against the same or an unrelated influenza virus antigen in vitro, and also suppressed protective Th1 responses against the bacteria in vivo (McGuirk et al. 1998). The induction of Tr cells against a pathogen may be a means for the host to control or terminate Th1 responses in vivo and thereby limit immunopathology and collateral damage to host tissue. However, it may represent a novel evasion strategy adopted by bacteria to subvert protective cell-mediated immunity. It is interesting that local Th1 responses are suppressed in the lungs and draining lymph nodes during acute infection of mice with *B. pertussis* (McGuirk et al. 1998). Furthermore, in infants and young children the disease is very protracted, with secondary infection in the lung.

In addition to the chronic viral and parasitic diseases, there are a number of other bacterial infections that are either persistent or associated with immunosuppression in vivo. Although there are a variety of explanations, including bacterial interference with antigen processing and presentation or production of anti-inflammatory cytokines by innate cells, the induction of Tr cells by the pathogen may also contribute to this immunosuppression. With the exception of the *B. pertussis* study, bacteria-specific Tr cells have not been cloned or specifically identified at the polyclonal level. However, there is indirect evidence of suppressor, anergic, or IL-10- or TGF-β-secreting T cells in a number of bacterial infections, including infections with *Mycobacteria*, *Pneumocystis*, *Helicobacter*, and *Lactobacillus* spp.

A proportion of patients with active pulmonary TB have defective DTH responses to mycobacterial antigens (i.e. they do not mount a skin test response to PPD) and have a poor clinical outcome. T cells from these anergic patients secreted IL-10, but not IFN-γ, after in vitro stimulation with PPD, whereas PPD skin test-reactive patients secreted IL-10 and IFN-γ; IFN-γ production is augmented in T cells from anergic patients by the addition of anti-IL-10 (Boussiotis et al. 2000). Defective phosphorylation of TCRζ and defective activation of ζ-associated protein (ZAP)-70 and the mitogen-activated protein (MAP) kinase extracellular regulated kinase (ERK) was also demonstrated in the anergic T cells stimulated with anti-CD3 and anti-CD28 (Boussiotis et al. 2000). Furthermore treatment of mice with killed *Mycobacterium vaccae* induces allergen-specific $CD4^+CD45RB^{Lo}$ Tr cells which are capable of protecting against airways inflammation, through an IL-10- and TGF-β-dependent mechanism (Zuany-Amorim et al. 2002). In a study of *Pneumocystis carinii*-infected mice, it was demonstrated that Tr cells may function to control the Th1 response, which are responsible for eliminating the bacteria and mediating lung immunopathology. Adoptive transfer of $CD4^+CD25^+$ T cells delays bacterial clearance, but also prevents development of lethal pneumonia by $CD4^+CD25^-$ T cells (Hori et al. 2002). $CD4^+$ T cells from *Helicobacter hepaticus*-infected mice block colitis in recombinant activation genes $RAG^{-/-}$ of mice induced by transfer of *H. hepaticus*-specific T cells from IL-$10^{-/-}$ mice; suppression was mediated by IL-10 and has been attributed to *H. hepaticus*-induced Tr cells (Kullberg et al. 2002). *Lactobacillus paracasei* has been shown to induce IL-10 and

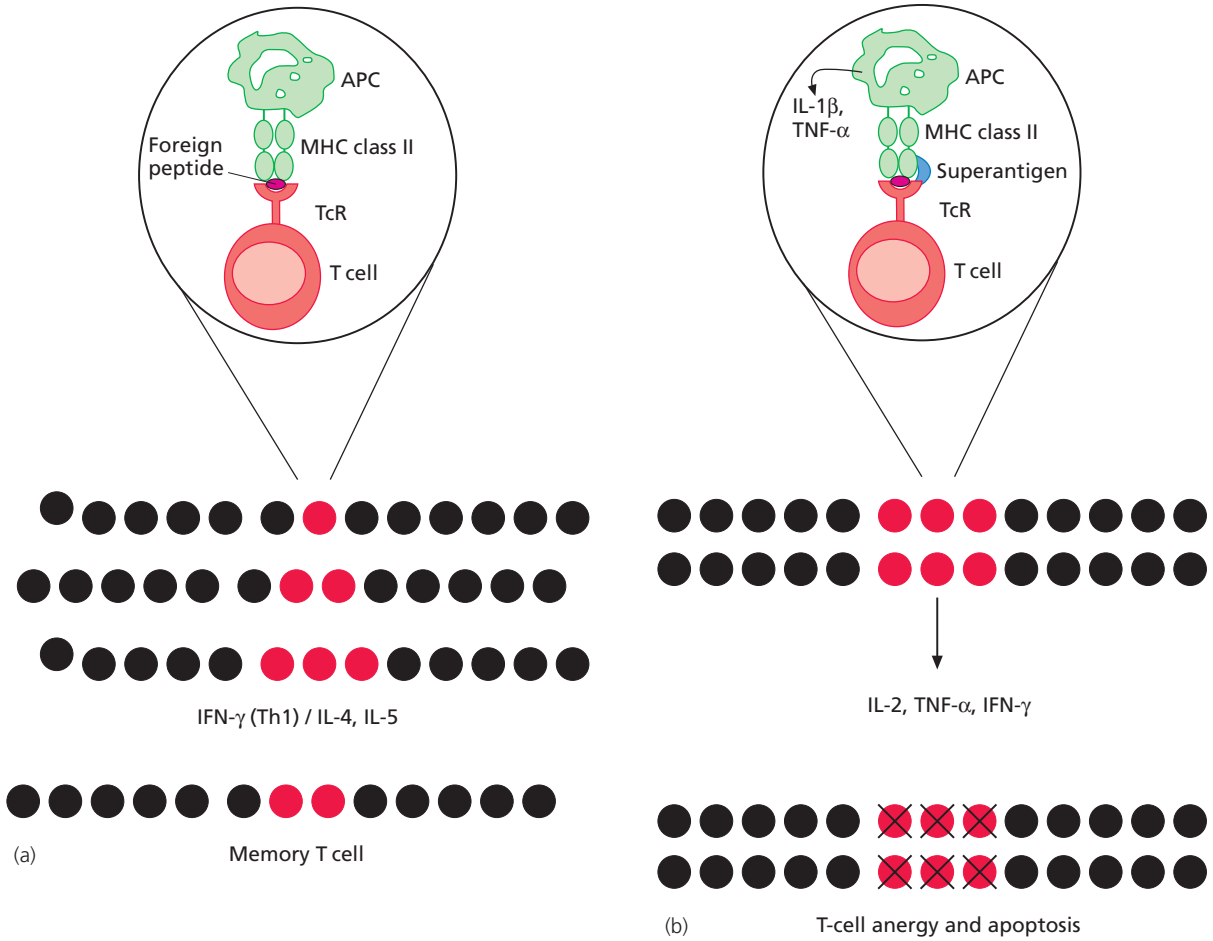

Figure 7 *Superantigen versus conventional antigen activation of T cells.* **(a)** *Conventional foreign antigens are processed by antigen-presenting cells (APCs) and peptide fragments associate with variable regions in the groove of the MHC class II molecule, and interact with variable regions of the T-cell receptor (TCR). Only a low frequency of T cells specific for the peptide MHC complex are activated. Activated T cells proliferate and secrete cytokines, and then a proportion goes on to become memory T cells.* **(b)** *Bacterial superantigens bind as intact proteins to MHCII molecules outside the foreign peptide binding groove and crosslink with the variable region of the TCR β chain on T cells. Following this encounter the APC produces proinflammatory cytokines, including interleukin IL-1β and tumor necrosis factor α (TNF-α) and all T cells bearing that Vβ element are activated to produce Th1-type cytokines IL-2, TNF-α, and interferon γ (IFN-γ), and then undergo apoptosis. This results in massive secretion of proinflammatory cytokines and deletion of the T cells expressing that particular TCR Vβ chain.*

IL-12 production by murine spleen cells, and addition of bacteria to cultures of $CD4^+$ T cells stimulated with alloantigens suppresses IFN-γ, IL-4, and IL-5 production and expands a population of Tr-type cells that secreted IL-10 and TGF-β (von der Weid et al. 2001).

Although there is evidence that iDCs drive the induction of anergic or Tr cells, there is growing evidence that differentiation of Tr cell from naïve precursor T cells appears to require DCs in a particular activation status distinct from that required to drive Th1 or Th2 cells. A number of bacterial products that bind to PRRs on macrophages and DCs have been shown to activate DC1 and DC2 in subtypes that direct naïve T cells into Th1 or Th2 respectively (see Figure 3, p. 13). It has now been reported that FHA from *B. pertussis* may drive a third population of DCs, termed 'DCr', that drive the induction of Tr1 cells (McGuirk and Mills 2002). IL-10 and IFN-α have been shown to function in differentiation of Tr1 cells, whereas TGF-β and IL-4 have been implicated in the differentiation of Th3 cells. FHA stimulates macrophages and DCs to secrete IL-10 and experiments with TCR transgenic mice demonstrated that FHA-stimulated DCs drove induction of Tr1 cells and this was switched to a Th1 phenotype in the presence of anti-IL-10 antibody. A number of bacteria have been shown to stimulate IL-10 production by macrophages and DCs and, although this may directly contribute to their anti-inflammatory and immunosuppressive effects, it may also create the appropriate cytokine milieu for the induction of Tr cells in vivo. There is also evidence that DCs or other innate cells in the lungs (Akbari et al. 2001), Peyer's patch (Iwasaki and Kelsall 1999), and liver (Khanna et al. 2000) have a propensity either to secrete IL-10 or to promote the induction of

anergic T cells. This may facilitate the induction of Tr cells at mucosal surface, where they may play major roles in maintaining tolerance against inhaled antigen, food antigens, and commensal. However, these DCs may be exploited for the induction of antigen-specific Tr cells by many pathogenic bacteria, viruses, and parasites that invade the body through the respiratory tract, gastrointestinal tract, or other mucosal surfaces.

Superantigens

Superantigens are microbial toxins with potent immunomodulatory properties, altering normal immune responses to foreign antigens and promoting autoimmune diseases. Unlike conventional T cells where the TCR binds to processed peptide antigens in the groove of an MHC molecule, superantigens bind outside the grove of MHC and crosslink MHCII molecules with a variable region of the β chain of the TCR, forming a trimolecular complex that activates a much larger number of resting T cells than does conventional antigen (Figure 7). Furthermore, superantigens are presented to T cells by MHC molecules usually without the need for antigen processing. Superantigens activate proliferation, secretion of cytokines, including TNF-α, IFN-γ, and IL-2 by 20–25 percent of resting T cells, eventually resulting in anergy, apoptosis, and depletion of peripheral T cells expressing specific TCR Vβ chain, with a resultant immunosuppression. A number of pathogens including *S. aureus*, *S. pyogenes*, *Mycoplasma arthritidis*, *Y. enterocolitica*, *C. perfringens*, and *M. tuberculosis* secrete toxins, which act as superantigens (Fraser et al. 2000; McKay 2001). The best-studied superantigens include the families of staphylococcal enterotoxins and streptococcal pyrogenic exotoxins. These toxins cause food poisoning and toxic shock-like syndrome, and may contribute to autoimmune diseases by breaking tolerance to selfantigens (Fraser et al. 2000).

The enhancement of autoimmune diseases by superantigens appears to be related to enhancement of proinflammatory cytokine production. *M. arthritidis* mitogen (MAM), a superantigen secreted by *M. arthritidis*, induces type 1 cytokine secretion (IL-12, IFN-γ, and TNF-γ, but no IL-4 or IL-10) in arthritis-susceptible C3H/HeJ mice, but Th2 responses in arthritis-resistant BALB/c mice (Mu et al. 2000). In contrast, it has also been demonstrated that repetitive injection of staphylococcus enterotoxin induces a state of unresponsiveness characterized by lack of secretion of the type 1 cytokines IL-2 and IFN-γ. Unresponsive animals were found to have IL-10-secreting $CD4^+$ Tr cells capable of suppressing bacterial superantigen-reactive T cells (Noel et al. 2001). Conversely, it has been demonstrated that natural $CD4^+$ $CD25^+$ Tr cells (Pontoux et al. 2002) can control superantigen-induced proinflammatory cytokine production. Activation of T cells with superantigens in vivo can indirectly induce maturation of DCs into a phenotype distinct from LPS-matured DCs, with high MHCII and CD40 expression but low-to-moderate expression of CD80 and CD86 (Muraille et al. 2002). This DC phenotype is distinct from DC1 cells, suggesting that superantigens may not necessarily favor the induction of Th1 cells.

CONCLUSIONS

The immune system has developed highly sophisticated mechanisms for combating infectious diseases and is capable of eliminating most pathogenic bacteria that invade the host. However, many of these bacteria can cause severe disease, especially in naïve and immunocompromised individuals. This is largely a reflection of the success of pathogenic bacteria in evading or subverting protective immune responses. This chapter has detailed some, but by no means all, of the strategies adapted by bacteria to target different aspects of innate and adaptive immunity. Indeed this may be just the tip of the iceberg and, as a periodic review of the current literature on the immunology of infectious diseases will reveal, there is rapidly expanding knowledge of the interplay between pathogens and their host. We still have a great deal to learn about our own immune system by studying how pathogens have evolved to evade it.

Parasites (Greek: pará-sitos, i.e. 'eat together') are unicellular (protozoan) or multicellular (metazoan) organisms that live in a close relationship on or within their hosts and are able to affect them adversely by acquisition of nutrients, damage to body surfaces, or penetration into tissues. They continue to be an increasing health problem and create a substantial economic burden, especially in less developed areas within the tropics.

Compared with the 5000 genes found in *Escherichia coli* bacteria, parasites have of the order of 7 000–20 000 protein-encoding genes. This genetic complexity may be required for the organization of the eukaryotic cell apparatus, but it is likely that a substantial number of genes contribute to the maintenance of the very diverse lifestyles that are perfectly adapted to survival in intermediate and definitive hosts with extremely different environmental conditions. Many parasites are more nuisance than danger to humans; some can, however, cause severe disease.

It is a characteristic hallmark of parasitic diseases that they are chronic in nature, with or without an acute onset. Chronicity of disease clearly indicates that either the immune system is unable to eradicate the invading pathogen or the continuous struggle of the immune system to combat the invading organisms leads to a state of immunopathology. Chronicity of disease also implies that the parasites have the ability to subvert or evade the immune response. Protozoan parasites with their smaller genomes usually need a relatively short time to replicate, and therefore evade host immune responses, often through mechanisms based on quick mutational or adaptive changes such as variation of their surface antigenic coat. In contrast, helminths have much longer generation times and therefore employ an array of other evasion mechanisms. For some organisms, such as *Trypanosoma brucei*, and, more recently, for *Plasmodium* spp. the molecular basis for immune evasion is quite well understood, whereas for others, especially helminth infections, the underlying mechanisms are much less clear.

The morphological and genetic complexity and the remarkably divergent lifestyles of parasites make them extremely interesting and, at the same time, difficult to approach for immunological studies. Nevertheless, considerable achievements have been made in the last decade and some of the parasites, e.g. *Leishmania* spp., have become paradigmatic to the understanding of basic immunological principles. This knowledge has helped to disclose some of the many determinants that regulate the type, the course, and the intensity of immune responses. It is also a prerequisite to establish a rational basis for the development of prophylactic and therapeutic immune intervention measures.

PROTOZOA AND THE DISEASES THAT THEY CAUSE IN HUMANS

Among the parasitic protozoa there are five major groups: Apicomplexa, Kinetoplastida, Trichomonadida,

Diplomomnadida, and Amebida. Apicomplexans include *Plasmodium* spp., *Toxoplasma gondii*, and *Cryptosporidium parvum*, *Leishmania* spp., and *Trypanosoma* spp. belong to the kinetoplastid protozoa. *Trichomonas vaginalis* is grouped in the order Trichomonadida, and *Giardia lamblia* belongs to the order Diplomonadida. Pseudopodia-forming organisms such as *Entamboeba histolytica* are allocated to the order Amebida. During evolution apicomplexan parasites have adapted to a life within host cells and have distinct organelles that are important for the invasion process. They infect different but distinct cell types depending on the stage of development. Flagellated organisms live outside (*T. vaginalis*, *G. lamblia*) or inside the body, either extracellularly within the bloodstream or the brain (*T. brucei*) or intracellularly in many different cell types (*T. cruzi*) or restricted to a narrow spectrum of host cells such as granulocytes, macrophages, dendritic cells, or fibroblasts in the case of *Leishmania* spp.

Plasmodium spp.

Four different species of *Plasmodium* are responsible for malaria in humans, i.e. *P. falciparum* (for genome sequence, see Gardner et al. 2002), *P. vivax*, *P. malariae*, and *P. ovale*. During a blood meal of an infected female anopheles mosquito (for genome sequence of *A. gambiae*, see Holt et al. 2002) they enter the bloodstream directly as sporozoites. Within less than an hour the sporozoites invade hepatocytes by recognizing glycosaminoglycans on the liver cells, through binding via a set of surface proteins called circumsporozoite protein (CSP) and thrombospondin-related adhesive protein (TRAP) (Muller et al. 1993; Frevert 1994). Inside the hepatocyte, the parasites divide and release merozoites that bind to different glycoproteins on erythrocytes, e.g. to a distinct region of erythrocytic glycophorin A via surface proteins called erythrocyte-binding antigen (EBA) (175) and merozoite surface proteins (MSP) (Orlandi et al. 1992; Perkins and Rocco 1988) or by ligation of the parasite protein P. falciparum erythrocyte membrane protein 1 (PfEMP1) to the complement receptor CR1 (CD35). Interestingly, the CR1 receptor is increased 40- to 70-fold in malaria-exposed African populations (Krych-Goldberg et al. 2002). Inside the erythrocyte, the parasites start to differentiate and multiply to produce more merozoites, which, after rupture of the red blood cell, are released to infect new erythrocytes. Some parasites differentiate into gametocytes which, after ingestion by a blood-feeding mosquito, fuse to form a zygote; this subsequently gives rise to the development of sporozoites that can infect additional humans.

After a typical incubation time of 1–2 weeks, the key features of acute plasmodial disease comprise sudden fever attacks caused by abrupt release of merozoites together with ruptured erythrocytes and its contents and, more seriously, cerebral coma and multi-organ failure (kidney, liver, lung). The latter results from reduced microcirculatory blood flow caused by structural and functional changes of infected (and uninfected) erythrocytes (Dondorp et al. 2000). Parasitized red blood cells adhere to endothelial cells primarily via PfEMP1 proteins, which are expressed on modified membrane regions called 'knobs' and bind to endothelial CD36, intercellular adhesion molecule (ICAM), thrombospondin, platelet endothelial cell adhesion molecule-1 (PECAM-1), and, especially in the placenta, hyaluronic acid and chondroitin sulfate A. In later stages of the disease, anemia develops together with splenomegaly accompanied by leukopenia and thrombocytopenia.

Protective immunity against *Plasmodium* spp. develops slowly and it may be necessary for a child born in a malaria-endemic area to be exposed to many successive infections for a number of years before developing any resistance; complete protection may never be achieved. The apparent inefficacy of antimalarial immunity may be explained by the parasite subverting or evading the immunological armamentarium by sequestration, poor immunogenicity of its antigens, or antigenic diversity and variation. The recent deciphering of the genome of *P. falciparum* (Gardner et al. 2002) has shown that many genes at the end of the parasite's chromosomes code for the expression of different versions of merozoite proteins on the surface of infected erythrocytes, thus confounding the immune responses that aim to destroy the infected cells.

Toxoplasma gondii

Infection with *T. gondii* is one of the most common parasitic infections of humans, other mammalians, birds, and other vertebrates. It is found worldwide with nearly one-third of the world population being exposed. In immunocompetent people, it does not cause serious illness but can lead to devastating disease in those with immunoincompetence, including fetuses and children born to mothers with primary infection during pregnancy as well as in patients with AIDS.

The definite host for the parasite is primarily the young cat (Dubey et al. 1970; Sibley et al. 1998; Carruthers et al. 2000; Brecht et al. 2001). In cats, the parasite's sexual stage occurs intracellularly in intestinal epithelia, leading to non-infective oocysts that are passed with the cat's feces in feed, water, or soil. After sporulation ('ripening') infective oocysts develop. When ingested by intermediate hosts (humans, livestock animals), the oocysts release tachyzoites. Ubiquitously expressed glycosaminoglycans on the host cells recognize secreted toxoplasmal proteins (MIC1 and MIC2), leading to adherence. Invasion occurs actively through an actin–myosin-based process with which the parasites glide, rotate, and undulate into a vacuole that is created mostly from material secreted by apical organelles

(Sibley et al. 1998; Mordue et al. 1999b; Brecht et al. 2001). Through formation of the vacuolar membrane, it selectively excludes host cell plasma membrane proteins (Mordue et al. 1999a) and thus may fail to induce host cell signaling. Within the cell, *Toxoplasma* spp. remain inside the parasitophorous vacuole by inserting their own proteins into the membrane. This prevents acidification and fusion with the lysosomal contents (Carruthers et al. 2000). The parasites divide until the host cell is filled with parasites and transform into bradyzoites. Neighboring cells may be infected or – especially after the host has acquired immunity – the bradyzoites may build up a cystic membrane with hundreds of parasites that can persist for prolonged periods of time, possibly life-long. When cysts, e.g. in undercooked or raw meat, are eaten by another mammal, the bradyzoites can continue the life cycle. After ingestion by a cat, they can initiate the sexual cycle.

In immunocompetent people, most infections are asymptomatic or show mild clinical signs such as low-grade fever, fatigue, headache, and muscle and joint pain. More common is painful swelling of cervical lymph nodes. In people with impaired cellular immunity, as occurs after HIV infection with CD4 T lymphocytes of less than 50/μl peripheral blood, *Toxoplasma* spp. can cause a life-threatening disease. On liberation of bradyzoites from the cysts, about one-third of AIDS patients develop a necrotizing focal encephalitis with dissemination in various organs, often with lethal consequences. Another extremely susceptible population are unborn children who acquire *T. gondii* from women who experience a primary infection during pregnancy. Depending on the intensity and the time point of infection, stillbirth, hydrocephalus, or intracerebral calcification including the retina can occur.

Encystment of toxoplasma parasites is dependent on a robust acquired immunity involving dendritic cells, CD4 and CD8 lymphocytes, as well as interleukin-12 (IL-12) and interferon-γ (IFN-γ) as the central protective elements (Yap and Sher 1999; Scanga et al. 2002).

Cryptosporidium parvum

Cryptosporidia are apicomplexan parasites that have long been known as pathogens for livestock animals, especially calves. The first case of human cryptosporidiasis was reported only in 1976 (Meisel et al. 1976; Nime et al. 1976). The organism is spread from animals to humans but also from person to person, and is often transmitted by contaminated water. It is distributed throughout the world. Its risk for human health is exemplified by a recent outbreak as a result of failure of appropriate water purification processes in the USA (MacKenzie et al. 1994).

The life cycle of *C. parvum* is confined to the microvillous region of the intestinal epithelia within one definitive host. After ingestion of infective oocytes, sporozoites are released which invade enterocytes and form an intracellular but extracytoplasmic parasitophorous vacuole, which is limited by a four-layer membrane. After multiplication and differentiation, merozoites are released which can infect other enterocytes through autoinfection. Some merozoites develop into sexual stages that produce a thick-walled oocyst after fusion in the parasitophorous vacuole, which is shed through the feces and can infect other individuals.

Infection with *C. parvum* may be without any symptoms or may lead to a self-limiting disease with watery diarrhea, nausea, and abdominal cramping for a few days. In patients with underlying illnesses affecting the adaptive immune system such as those with AIDS or on immunosuppressive therapy, the intensity and duration of gastrointestinal symptoms can be life threatening. In addition to the gastrointestinal tract other epithelia such as those of the respiratory system or the gallbladder can be infected (Chen et al. 2002).

Despite substantial knowledge of the life cycle and excellent morphological evidence, comparatively little is known about the immunobiology of *C. parvum* infection as a result of the lack of an appropriate animal model and the inability to culture sufficient numbers of parasites in vitro. Existing evidence suggests, however, that, very similar to Toxoplasma infection, the adaptive cellular immune system is dominant over the humoral immune system to provide protection. The increasing number of genes or genomic DNA fragments registered in GenBank (www.ncbi.nlm.nih.gov/cgi-bin/genbank?Cryptosporidium) will greatly facilitate our understanding of immunological and basic biology aspects in the near future.

Trypanosoma spp.

TRYPANOSOMA BRUCEI COMPLEX (AFRICAN TRYPANOSOMES)

Based on similarities in geographical distribution, infectivity to humans, life cycle, morphology, and major biochemical features, the *Trypanosoma brucei* complex comprises three subspecies: *T. b. brucei*, *T. b. gambiense*, and *T. b. rhodesiense*. In this chapter they are referred to as *T. brucei*. The parasites are endemic in many countries of sub-Saharan Africa.

Metacyclic forms of *T. brucei* are transmitted by the bite of an infected tsetse fly (*Glossina* spp.) through contaminating saliva. After inoculation, they remain at the infectious site for a short time and induce a local inflammatory response of the subdermal tissue (‘chancre’). Subsequently, they are disseminated throughout the body once they have gained access to lymph and blood vessels. They multiply rapidly extracellularly and lead to different waves of parasitemia, which are accompanied by systemic inflammation with perivascular infiltration of leukocytes. In later stages of the disease, they enter the central nervous system (CNS), the heart, and endocrine

organs. CNS involvement is associated with a wide array of behavioral changes, ranging from aggressiveness to lethargy, somnolence ('sleeping sickness'), or death.

The way in which *T. brucei* causes disease is unclear, but the success of infection is linked to the parasite's ability to select for the expression of one out of hundreds of genes that code for a major surface coat antigen, the variant surface glycoprotein (VSG) (Donelson et al. 1998; Andrews 2002; Berriman et al. 2002). Each VSG induces a strong and specific antibody response, which clears up to 99 percent of the parasites bearing it during a given wave of parasitemia. A minor population of pre-existing parasites (between 0.000001 and 1 percent) expresses a different VSG and thus is not recognized by the specific antibodies. This population then can outgrow and give rise to the next wave of parasitemia, until the new immune response leads to their demise; this scenario is repeated several times.

TRYPANOSOMA CRUZI (NEW WORLD TRYPANOSOMES)

T. cruzi parasites are endemic in several Central and South American countries and they are the cause of Chagas' disease. Metacyclic trypomastigotes are deposited on the skin through the feces of blood-feeding triatomine bugs. They are motile and have the capacity to penetrate abraded skin or the wound caused by the bite of the bug. They can also cross the conjunctiva or nasal and oral mucosa, if bug feces reach these surfaces. Once inside the host, they enter phagocytic or nonphagocytic cells and convert into replicating amastigotes. The responsible attachment and invasion receptors and ligands are not well defined. Contact of trypomastigotes with the host cells leads to the recruitment of host cell lysosomes to the plasma membrane, where both coalesce and fuse, forming a compartment in which the parasites enter to form a phagosome (Andrews 2002) (www.archive.bmn.com/supp/part/andrews.html). This process is initiated by a parasite oligopeptidase B, which triggers transient elevation of the intracellular calcium level in the host cell (Burleigh 2000) and is dependent on the activation of the transforming growth factor β (TGF-β) signaling pathway. *T. cruzi* resides only transiently within the phagosome, because it releases membrane-dissolving molecules that allow the parasite to enter the cytoplasm. After nine cycles of binary replication, the amastigotes differentiate into trypomastigotes and are released in large numbers into the bloodstream and can infect other cells or a triatomine vector.

T. cruzi leads to a number of clinical manifestations, which include lymphadenopathy, generalized edema, enlargement of the heart with arrhythmias, dysfunctions in the alimentary tract with loss of peristalsis, severe obstipation, and progressive dilation of the gut. These signs result from chronic infection of the respective cells, although chronic autoimmune inflammation has been suggested as an underlying pathogenic principle. In patients with AIDS the organism commonly crosses the blood–brain barrier with fatal meningoencephalitis. Both antibodies and T cells are important antiparasitic effector mechanisms necessary to combat the trypanosomal infection at intra- and extracellular locations (Ouaissi et al. 2002).

Leishmania spp.

Leishmania spp. are parasites that infect humans in all continents except Australia. Eighteen species are known to cause human disease. Some lead to localized cutaneous disease, whereas others cause systemic disease.

Leishmania spp. are transmitted by the bite of sand flies (*Phlebotomus* and *Lutzomyia* spp.). In the gut of the insect they develop as flagellated motile promastigotes, which are highly infective in their metacyclic stage – found in the salivary glands (Sacks 2001). During blood feeding they are deposited, together with the sand fly's saliva, in the epidermal and dermal tissue. Saliva components greatly facilitate the establishment of an infection and reduce the infectious dose required to establish a successful infection (Belkaid et al. 2001; Zer et al. 2001). Promastigotes have a dense layer of a lipophosphoglycan (LPG) and a 63-kDa glycoprotein (gp63) zinc metalloprotease, which both serve as virulence factors (Sacks and Kamhawi 2001; Joshi et al. 2002). The outer portion of the LPG extends from the surface of the parasite to form a glycocalix, which activates host complement and leads to deposition of C3 on the parasite's surface. At the same time the glycocalix and gp63 prevent membrane attack complex (C5–C9) being inserted into the parasite's membrane. The C3-coated promastigotes attach to complement receptors 1 and 3 (CR1, CR3) on macrophages. On reorganization of the actin–myosin cytoskeletal apparatus (May and Machesky 2001) of the host cell membrane, components of the endoplasmic reticulum (ER) are recruited close to the surface of the cell, where they fuse with the plasma membrane, which opens up at the site of parasite contact. The parasite then slides into the open ER, whereas the plasma membrane is resealed and the formation of the phagosomal vacuole is initiated (Gagnon et al. 2002).

At very early stages of infection, *Leishmania* spp. are phagocytosed by neutrophilic polymorphonuclear granulocytes (PNG), which are attracted to the site of infection through a parasite-derived chemotactic factor (Van Zandbergen et al. 2002). Inside the PNGs, they delay the usually rapidly occurring granulocytic apoptosis through inhibition of a caspase 3-related pathway (Aga et al. 2002). Thereby they are shielded from the hostile extracellular host milieu until ingestion by mononuclear cells. Once inside the definitive host cells, *Leishmania* are directed to the lysosomal compartment, where they transform into nonflagellated amastigotes, persist, and replicate. Through various mechanisms they inhibit

signaling events that would normally lead to macrophage activation and parasite killing. However, interferon-γ (IFN-γ) is able to activate macrophages to overcome this parasite-induced block and is able to promote parasite killing by inducing inducible nitric oxide (NO) synthase expression and NO production (Bogdan 2001). The murine mouse model of subcutaneous *L. major* infection has become paradigmatic for studying the adaptive immune response with respect to the roles of T-helper 1 (Th1) and T-helper 2 (Th2) lymphocytes in vivo.

In humans, disease develops as a result of incomplete parasite killing. This in turn results in chronic lesions at skin or mucosal sites (*L. major*, *L. amazonensis*, *L. braziliensis*, and *L. chagasi*) or in internal organs rich in macrophages such as the liver, spleen, or bone marrow (*L. donovani*, *L. infantum*, and *L. braziliensis*). In addition, excessive and damaging immune responses to the parasite may cause serious and debilitating disease (mucocutaneous leishmaniasis caused by *L. amazonenis*).

Entamoeba histolytica

Six species of amoebae are commonly found in the human gastrointestinal tract, of which *E. histolytica* is of medical importance. The organism is taken up with contaminated drinking water as an infectious cyst. Intraintestinally, the cyst wall is dissolved and gives rise to trophozoites, which can either form new cysts or occasionally penetrate the mucosa and disseminate to other organs, with serious implications such as amoebic colitis or liver abscesses. *E. histolytica* trophozoites are able to kill epithelial and immune cells rapidly. The killing is contact dependent and mediated by the trophozoite, Gal/GalNac lectin, which recognizes and binds host cell glycoconjugates and is associated with the release of pore-forming proteins (Leippe et al. 1994; Petri et al. 2002). Once lectin-mediated host–parasite contact occurs, the parasite activates host cell caspase 3, resulting in immediate cell death by apoptosis (Huston et al. 2000). Both local and systemic humoral and cellular immunity appear to play a role in protection, which may open up a window for the development of a vaccine (Miller-Sims and Petri 2002).

IMMUNITY, PERSISTENCE, AND EVASION IN INFECTIONS WITH PROTOZOAN PARASITES

As has been outlined so far, protozoan parasites have an extremely diverse array of lifestyles. This poses a challenge to the immune system which goes far beyond what is well understood by using experimental model antigens such as bovine serum albumin or relatively simple organisms such as viruses. Instead, the innate immune response has to recognize, at the same time, a vast variety of molecular patterns at one or different sites in the body. In addition, host defense has to be extremely flexible in tailoring the appropriate adaptive immune response as a result of the developmental stages through which many parasites go. The site of infection (skin, mucosa, conjunctiva, direct inoculation by blood-feeding arthropods with saliva), the number of infecting organisms, the parasitic lifestyle (intracellular or extracellular, within a vacuole or in the cytoplasm, replicative or not, production of antigenically distinct progeny), the overall constitution of the host's immune system (influenced by genetic susceptibility/resistance, age, nutritional status, previous experience with parasitic or other infections) are all determinants for what constitutes a protective immune response.

Paradigmatic experimental work on the analysis of the immune response to *L. major* after experimental subcutaneous syringe infection of different inbred mouse strains has shown the importance of the development of a polarized Th1 or Th2 answer. Animals that are able to mount an adaptive response dominated by Th1 lymphocytes survive and are resistant to re-infection, whereas those with a Th2-biased response are highly susceptible and succumb after exposure (for review, see Solbach and Laskay 2000). From these findings it was expected that, in all parasitic infections, a Th1 response would have protective effects, whereas Th2 responses would be associated with a failure to resist infection. It appeared, however, that this perception was not true. Work on immunity to intestinal helminths showed an exactly opposite pattern of severity of disease and the type of adaptive immune response: Th2-type responses in many cases allowed the resolution of infection, whereas Th1-type responses promoted chronic and nonprotective courses of the disease (MacDonald et al. 2002). This led, for a while, to the simplistic concept that a Th1 response alone might be sufficient for immune control of intracellular protozoa whereas a Th2 response, being responsible for the development of antibodies and the dampening of a potentially overreacting Th1 cellular immune response, was meant to keep extracellular parasites restricted. It soon turned out, however, that a delicate balance between Th1 and Th2 immune responses is responsible for shaping the outcome of most, if not all, parasitic infections. It also became clear that this balance varies considerably over time and controls the production of cytokines such as IFN-γ, the interleukins IL-4, IL-10, and transforming growth factor β (TGF-β). At the same time, T cells by themselves are under the tight control of cytokines which constitute the complex mixture of humoral factors at the infectious site. The result of all these determinants is responsible for activation of the protective antiparasitic effector arms.

The kinetics and magnitude of cytokines produced by T cells is determined by the initial interactions of the parasites with early inflammatory cells such as granulocytes and dendritic cells. They are equipped with an array of pathogen recognition receptors (PRR) on their surface. PRRs are activated by the parasite's pathogen-

associated molecular patterns (PAMP) and thus serve as innate 'master regulators' of the ensuing adaptive immune response, e.g. the PAMP-protein Tc52 from *T. cruzi* (which is also crucial for the parasite's survival) binds to the PRR Toll-like receptor 2 (TLR-2) on dendritic cells. This interaction induces host cell maturation and production of inflammatory chemokines, and protects mice from an otherwise lethal infection (Ouaissi et al. 2002).

In contrast to prokaryotes, many infecting eukaryotic parasites undergo a series of developmental changes during their establishment, development, or proliferation within the host. In consequence, although infected with only one given parasite species, the host is exposed to numerous sets of PAMPs as the infectious organism proceeds through its developmental pathway, e.g. infection with *Plasmodium* spp. exposes the host to four different extracellular life-cycle stages – the sporozoite, the merozoite, and the male and female gametocytes – plus the additional forms that live within the hepatocytes or erythrocytes. Although all these life-cycle stages share the expression of a basic set of genes, they also express stage-specific genes that code for the proteins required for successful completion of the life cycle. Thus, primary exposure to malaria leads to a series of immune responses directed to related, but antigenically distinct, organisms. The situation is even more complex in helminthic infections. Here, the larval form is often completely different from the adult worm or its progeny, and thus a whole series of different immune responses are initiated and maintained, e.g. eggs produced by adult schistosomes produce a Th2 response, whereas the worms themselves do not (Pearce and MacDonald 2002).

As a response to the antigenic complexity of parasites, the host creates a similarly complex set of immune responses. The relative contribution of the various immune mechanisms in operation throughout the course of infection is far from being understood, e.g. the early CD8 T-cell response is important in dealing with the hepatocytic stage of the infection with *Plasmodium* spp., but is largely irrelevant once the parasites have entered erythrocytes (Good and Doolan 1999). In contrast, in leishmania infections, CD4 T cells of the Th1 type mediate a protective immune response during the acute stage, whereas, for the induction of immunity with low-dose infections and its maintenance in chronic stages, CD8 T cells may be important (for review, see Solbach and Laskay 2000; Belkaid et al. 2002). Finally, maintenance of multiple effector responses, including antibodies, CD4 Th1 cells, and CD8 T cells, is required for the control of *T. cruzi* infections in both the acute and the chronic stages (Tarleton 2001).

In most parasitic infections the immune system sees and responds to a complex array of antigens, possibly with some exceptions, where a restricted number of antigens is dominant, e.g. *T. brucei* populations express for a brief period a given set of variant surface glycoprotein acronym>VSG, and in *L. major* infection of BALB/c mice the leishmania homolog of the receptor for activated c kinase (LACK) antigen is immunodominant (Schilling and Glaichenhaus 2001). The complexity in the immune responses makes it a challenge to develop an appropriate set of vaccine antigens that will elicit the appropriate protective effector mechanisms at relevant sites of infection, i.e. either in the tissues or at mucosal surfaces.

Most parasites survive within most of their hosts for long periods, thereby causing chronic infection (and in some cases chronic disease) and long-term stimulation of the immune system. From an evolutionary point of view, chronicity of parasitic infections indicates success for both the parasite and the host, because both are able to survive with each other for a long time. Recent experimental and clinical evidence suggests that immune responses induced by chronic helminthic infections during early life via the anti-inflammatory activity of IL-10 may shape the development of the immune system towards a Th1 bias such that it prevents immune dysfunctions that result in diseases such as allergy (van den Biggelaar et al. 2000; Bashir et al. 2002; Yazdanbakhsh et al. 2002).

Antigen variation

Chronicity of infection requires that the parasite must in some way be able to evade the immune attack to avoid its own elimination. Some protozoan parasites evade the immune response by sequential variation of their antigenic coat. African trypanosomes live extracellularly in an environment with high concentrations of antibodies which they induce themselves. They evade immune responses by selecting for the expression of one gene from a repertoire of up to 1000 variant genes through transcriptional activation. These genes encode the monomolecular VSG. VSG is composed of glycosylphosphatidylinositol (GPI)-anchored homodimers that are identically oriented and densely packed (10^7 molecules/cells) on the membrane surface. The repetitive VSG elements are scanned by B cells, which become activated without the help of T lymphocytes to produce a rapid IgM response. Within the parasite population, however, a spontaneous VSG gene switching occurs with one switch in 10^2–10^6 cells (Turner 1997). In consequence, the immune response occurring at a given time is appropriate and successful at killing trypanosomes through antibodies directed against the dominant surface antigens. However, the switch in antigen phenotype of an initially small population of parasites allows their expansion until sufficient antibodies are produced that recognize the new VSG variant. In this situation, the host eventually dies without ever completely eliminating the organisms from the body.

Although VSG-specific antibodies provide an important mechanism for controlling trypanosome numbers in the vasculature, antibodies alone are not sufficient to provide a significant level of host resistance. For control of parasites residing in the tissues, an early Th1 response with IL-12-driven and IFN-γ-dependent activation of macrophages is indispensable. This T-cell response is mainly induced by antigens that stem from an internal subregion of the VSG molecules which are liberated from the surface coat.

Antigenic variation is also employed by malaria parasites to avoid destruction by immune mechanisms (Kyes et al. 2001; Beeson and Brown 2002). Once the parasites have gained entry into the erythrocytes, they modify the infected cells with several proteins, which make them 'sticky' to the endothelium (Smith et al. 2002). One of the principal parasite-induced antigen on the red blood cell (RBC) surface is the PfEMP1 which is encoded by a clonally variant, multicopy, nonallelic family termed '*var*'. Modification of the erythrocyte's surface can be regarded as an important adaptation because it prevents the parasitized RBCs from being swept to the spleen, where they would be removed as a result of the aberrant shape that they acquire when parasitized. This advantage of course bears the risk of being identified by the immune system. In fact, antibodies specific for PfEMP1 can prevent the adhesion of parasitized cells to endothelial cells, thereby facilitating sequestration to the spleen. In response, the parasite selects for expression of one out of about seventy of PfEMP1-encoding genes at a given time, thus confounding the immune responses that aim to destroy the infected cells. Genome-wide analysis has identified more than 200 plasmodial genes which are likely to be involved in immune evasion, most of which are found near the ends of the chromosomes (Gardner et al. 2002).

Immediately after inoculation, plasmodium sporozoites circulate for a short time as extracellular organisms rich in surface circumporozoite protein (CSP). CSP is an antigen with multiple tandem repeats which induces a polyclonal Th cell-independent B-cell response. Plasmodia overcome this response by sloughing off their surface CSP coat, thus withdrawing the targets from the attack of antibodies (Ramasamy 1998).

Antigenic variation has also been observed in infections with the intestinal flagellated parasite *G. lamblia*. During infection, the parasite survives the host's reactions by undergoing continuous antigenic variation of its major variant surface protein (VSP). VSPs from *G. lamblia* are cysteine-rich proteins with considerable heterogeneity in size. In vivo, the VSPs expressed by the parasite population continuously diversify under the selection pressure of IgA antibodies and proteases secreted by intestinal cells (Muller and Gottstein 1998).

Intracellular refuge and its consequences

Intracellular residency of protozoans such as *Trypanosoma cruzi*, *Toxoplasma gondii*, or *Leishmania* spp. protects them from detection by defense systems. This advantage, however, requires mechanisms that assure survival and replication within that shelter. In the initial phase of the infection the host cells in many cases are from the macrophage lineage or granulocytes (Aga et al. 2002). They have the potential to inhibit the replication or to kill the microbes, once they become activated to do so. Many parasites have developed strategies to subvert this cellular activation. Metacyclic forms of *Leishmania* spp., for example, bind different sets of entry ligands that contribute to silent entry. These include binding and uptake via CR1 and CR3 receptors, scavenger receptors, the mannose fucose receptor (Solbach and Laskay 2000), or receptors that recognize phosphatidylserine. The last strategy, which is also employed by helminthic schistosomes, fakes the host cell because it signals (falsely) apoptotic structures that are considered to be dealt with without induction of inflammation (Freire-de-Lima et al. 2000; Freitas Balanco et al. 2001; Luder et al. 2001; Van Der Kleij et al. 2002). Other mechanisms include the generation of a 'safe' compartment inside the cell, e.g. *T. cruzi* parasites secrete a lytic protein that releases the parasites into the cytoplasm, thus escaping fusion of the phagosome with the lysosome and its toxic components. *L. donovani* and *T. gondii* create a parasitophorous vacuole that does not fuse with lysosomes. They can also inhibit the acidification of the vacuole or inhibit toxic proteases within the phagolysosome (Mauel 1996).

Once inside the cell, the parasites can suppress the triggering of the respiratory burst and the production of NO or activating cytokines such as IL-1β or IL-12 (Alexander et al. 1999; Bogdan and Rollinghoff 1999; Bogdan 2001). On the other hand, infected macrophages may be induced to overproduce cytokines such as IL-10 or TGF-β which dampen antimicrobial effector mechanisms exerted by IFN-γ-producing natural killer (NK) cells or T lymphocytes.

Activation of the adaptive immune system requires that the infected cells are ready for peptide processing, for antigen presentation via the class I or class II major histocompatibility complex (MHC) pathway and for expression of co-stimulatory molecules. All of these components are inhibited or deviated in parasitized cells depending on the intracellular lifestyle and the direction of the protein release into the different antigen presentation pathways (reviewed in Bogdan and Rollinghoff 1999). An alternate strategy is employed by parasites such as *T. cruzi* which release many different or related proteins of the *trans*-sialidase family into the class I MHC-processing pathway. Immunogenic peptide frag-

ments from these proteins could lead to suboptimal adaptive immune responses either by competing with each other for MHC binding or by acting as inhibitory altered peptide ligands for each other (Vidal and Allen 1996; Plebanski and Hill 2000).

Intracellular life is not restricted to macrophages or erythrocytes but also includes cells found in muscular tissue (chronically infected with *T. cruzi*) or in the CNS (chronically infected with *T. gondii*). Very little is known about the reasons for this tissue propensity but it is tempting to speculate that factors such as anatomical barriers for immunological scanning, poor antigen-presentation capacity of the host cells, and an 'anti-inflammatory' environment all play a role.

HELMINTHS AND THE DISEASES THEY CAUSE IN HUMANS

Helminths are a major public health problem in economically disadvantaged populations and over 2 billion people are affected worldwide (Crompton 1999).There are three major groups of helminth parasites: trematodes, cestodes, and nematodes. Most helminths dwell in the lumen of the gut, and many live in accessory organs of the gastrointestinal tract. Others are adapted to a life within host tissues such as the blood or connective tissue.

Furthermore, helminths have complex life cycles including adult worms, as well as several larval stages that may penetrate the host skin, migrate through tissues, or have phases of arrested development. Except in very few cases, helminths do not replicate within their hosts, but produce offspring in the form of eggs or larvae. These have to reach a new host either by fecal–oral transmission of eggs, penetration of the skin by larvae, ingestion of larvae with contaminated meat of intermediate hosts, or by transmission through vector arthropods. In many species, adult helminths reach life spans of more than 10 years and thus establish long-lasting chronic infections. The worms are therefore exposed to very different environments in their hosts and have to cope with different local immune responses.

Trematodes

The human pathogenic trematodes can be grouped according to their localization: intestinal flukes (many species), liver flukes (*Opisthorchis*, *Clonorchis*, and *Fasciola* spp. as a potentially human pathogenic parasite), lung flukes (*Paragonimus* spp.), and blood flukes (*Schistosoma* spp.). The most important trematode helminths for human are *Schistosoma mansoni*, *S. japonicum*, and *S. haematobium*. Intermediate hosts are freshwater snails, which release cercariae that, by secreting a broad-spectrum elastase and other proteases, actively penetrate through the exposed skin of humans and migrate via the arterial system to the portal vein of the liver (*S. mansoni* and *S. japonicum*) or the blood vessels around the urinary bladder (*S. haematobium*). At these sites, the parasites mature and mate, and female worms produce hundreds of eggs every day. These traverse the wall of the gut or the bladder, and are released to the exterior, where they can infect the intermediate snail host. As the eggs are deposited in the vasculature, the bloodstream may also carry them into the liver or venous capillaries of the bladder, where they are trapped. Antigens released from eggs induce a vigorous Th2 response that orchestrates the formation of a granuloma, which separates them from the host tissue. The granulomatous lesions resolve after death of the encapsulated eggs, but they leave behind fibrotic scars with IL-13 being of central importance in the development of fibrosis. These pathological changes can give rise to portal hypertension or, in the bladder, they can significantly increase the risk of malignant cancer (Pearce and MacDonald 2002).

Cestodes

The most important cestodes (tapeworms) that infect humans are *Taenia saginata*, *T. solium*, and *Echinococcus* spp. The first two worms lodge in the human intestine in their adult stage and are transmitted through intermediate bovine (*T. saginata*) or porcine (*T. solium*) hosts, respectively. The adults produce eggs that, after release with human feces, are ingested by the intermediate hosts, where the larva (oncosphere) hatches and penetrates the intestinal barrier. It then migrates to muscles and other organs where the metacestode, often called a cysticercus, develops. Transmission to humans occurs by ingestion of undercooked meat; inside the gut; the metacestodes are activated and give rise to the adult tapeworms. If a person swallows eggs of *T. solium*, the larvae will hatch and go on to produce cysticerci in many tissues including the brain, eye, heart, and striated muscles.

The adults of *Echinococcus* spp. live in the intestine of canides such as foxes or dogs. The eggs are passed with the feces and have to infect an intermediate host. Eggs of *E. granulosus*, the dog tapeworm, usually infect ungulates such as sheep or cows, where the metacestode forms large liquid-filled cysts (hydatids), mostly in the liver. The eggs of the fox tapeworm *E. multilocularis* develop in small rodents, where the metacestodes proliferate in the liver in a tumor-like manner. After accidental ingestion of eggs by humans, metacestodes of both species may develop in the liver, lung, or brain, and cause severe disease.

Nematodes

Intestinal nematodes are the most prevalent human parasites on earth. Species such as *Ascaris lumbricoides*,

the hookworms *Necator* and *Ancylostoma*, the whipworm *Trichuris*, and, to a lesser extent, parasites such as *Trichinella* and *Strongyloides* are found in more than half of the world's population. Infection mostly occurs through the fecal–oral route, with the exception of hookworms and *Strongyloides* spp. that actively penetrate the host's skin. Most nematodes live exclusively in the intestinal lumen and only have a subtle pathogenicity. However, in association with malnutrition and undernutrition they contribute significantly to poor health in many parts of the world, because malnutrition promotes the establishment, survival, and fecundity of these parasites (Koski and Scott 2001).

More severe pathological changes are caused by filarial nematodes that are transmitted by blood-feeding insects. The adult worms live within the lymphatics or in the skin, and produce thousands of first-stage larvae (microfilariae) per day. *Wuchereria bancrofti* and *Brugia malayi*, the causative agents of lymphatic filariasis, are transmitted by mosquitoes such as *Culex*, *Anopheles*, or *Aedes* spp. The filariae cause severe pathological changes through inflammatory obstruction of the lymphatics, which can lead to swellings of the affected limbs ('elephantiasis'). *Onchocerca volvulus* is transmitted by the bite of black flies (*Simulium* spp.). The adult nematodes live within subcutaneous nodules and inflammatory reactions induced by the skin-dwelling microfilariae lead to alterations of the skin and ocular damage ('river blindness'). Recent research has deciphered that intracellular bacterial endosymbionts (*Wolbachia* spp.) of *Onchocerca* may be a valuable target for antibiotic therapy of human filariasis with doxycycline. This therapy lead to a block in microfilarial embryogenesis and, possibly, to a significant reduction in filarial pathology (Hoerauf and Brattig 2002).

IMMUNITY AND PERSISTENCE IN INFECTIONS WITH HELMINTHIC PARASITES

Most helminthic parasites survive within most of their hosts for long periods, thereby causing chronic infection (and in some cases chronic disease) and long-term stimulation of the immune system. From an evolutionary point of view, chronicity of parasitic infections indicates success for both the parasite and the host, because both are able to survive with each other for long periods. Recent experimental and clinical evidence suggests that immune responses induced by chronic helminthic infections during early life via the anti-inflammatory activity of IL-10 may shape the development of the immune system toward a type of response that prevents immune dysfunctions such as allergy and chronic inflammatory diseases (van den Biggelaar et al. 2000; Bashir et al. 2002; Yazdanbakhsh et al. 2002). In this sense helminth infections were even discussed to have beneficial effects in some circumstances (Pritchard and Brown 2001).

One of the hallmarks of helminths is their longevity, with life spans of more than 10 years not being exceptional. This persistence implies that helminths are able to evade the immune effector mechanisms of their hosts, e.g. by skewing the cytokine network toward a predominance of Th2-like responses. Patients with helminthic infections show abundant circulating T cells with a Th2-like response to parasite antigen, with concurrent pronounced IgG4 and IgE antibodies and a high eosinophilia (Mahanty et al. 1992; Williams et al. 1994). T-cell proliferation in patients is severely downregulated, probably as a consequence of a selective anergy or suppression of the Th1-type cells (Allen and Maizels 1996). Even light infections might have such effects, because, for example, a single experimentally implanted *Brugia malayi* filaria is sufficient to inhibit the proliferation of T lymphocytes (Loke et al. 2000). This type of setting favors the survival of established worms, without preventing the host from defending itself against other pathogens.

The induced changes allow not only the tolerance of established worms, but at the same time also protective immune responses against newly intruding larvae of the same species. The main effector mechanism against the larvae is antibody-dependent cellular cytotoxicity (ADCC) with IgE as the most important antibody and eosinophils as effector cells. This 'concomitant immunity' can be considered as a mechanism for the regulation of parasite density (Cox 2001). Therefore, worm burdens in balanced host–parasite relationships are typically low and are usually tolerated without inducing severe pathological effects. Helminthic diseases are usually associated with high worm burdens and in most cases are a consequence of host immune reactions, rather than being the result of direct effects of the worms.

As a cautionary remark, our understanding of immune responses against helminths and their evasion mechanisms is largely based on studies from animal models that investigate the reactions against human pathogenic parasites. Not all of these data have been substantiated by studies in humans. Unfortunately, animal models for human disease are lacking in many cases and, therefore, one has to resort to the study of animal parasites in their natural hosts and draw indirect conclusions.

With regard to the trematodes, the most complete picture of immune reactions and evasion mechanisms comes from the schistosomes. The invasive stages of schistosomes (schistosomula) activate complement and are the target of ADCC reactions as well as of activated macrophages. Efficient killing of the IgE-opsonized schistosomula seems to be a predominant mechanism of protective immunity, whereas adult schistosomes are resistant to immune attack (Butterworth 1998; Pearce and MacDonald 2002).

Adult cestodes affect their hosts mainly as competitors for nutrients and cause little pathogenicity. As the worms dwell in the gut lumen and the only direct contact with the host is through the attachment of the scolex, immune reactions are of limited importance. Established metacestodes are not eliminated by host immune responses, but their growth is influenced by host responses, as shown by differences of parasite proliferation in various inbred strains of mice (Gottstein and Hemphill 1997). The metacestodes develop from larvae ('oncospheres') which are released from ingested tapeworm eggs. They cross the intestinal wall and migrate through blood vessels to their final location. These oncospheres are highly susceptible to lysis by complement-fixing antibodies, which leads to a limitation of superinfections (Lightowlers and Rickard 1988).

Gut-dwelling nematodes reach the intestines either directly or by migration of the larvae through various host tissues. On their way they can be killed by ADCC and inflammatory reactions, particularly in the lungs. The adult stages in the gut are mainly affected by IgE-sensitized mucosal mast cells. After antigen contact, they release mediators that lead to an immediate overproduction of mucus by goblet cells and to an increase in intestinal motility. In consequence, the worms are rapidly expelled (Ahmad et al. 1991). Protective intestinal immune responses against helminths are entirely dependent on Th2 responses and can be ablated by a reversion of the immune response towards a Th1 type (Else and Finkelman 1998; Finkelman et al. 1999). It is currently not clear whether and to what extent reactions of this type occur in humans.

In infections with filarial nematodes, the immune response and the resulting immunopathology depend on largely unknown factors. A minority of exposed persons is able to prevent infections with as yet unknown mechanisms ('putatively immunes'), whereas another subset of individuals is susceptible to infection. Patients who develop pronounced Th2 responses tolerate microfilariae, whereas others develop ADCC reactions and are able to clear the microfilariae.

Immune evasion mechanisms of helminths

Evolution has matched the host's immune armamentarium with a multitude of strategies by which helminths evade and subvert the immune responses (Maizels et al. 1993). As a result of their large genome (about 10^8 base-pairs) and relative long replication times, helminths cannot outpace the immune system by mechanisms involving mutations and gene rearrangements, such as the antigen variation of protozoan parasites. However, it is conceivable that they invest a similar proportion of genes into other types of immune evasion strategies. As ADCC and inflammatory reactions are the main immune effector mechanisms against helminths, their evasion mechanisms are tailored towards specifically coping with:

- complement activation
- the effect of antibodies
- the cytotoxic effect of phagocytes
- antigen presentation
- skewing of the cytokine network.

The strategies are of different complexity and can be grouped into passive approaches such as immune avoidance and blocking of effector mechanisms, and diversion strategies targeting the balance of the immune system by specifically acting on the cytokine network.

Avoidance strategies

Many immune effector mechanisms, similar to complement activation and ADCC, are directed against the surface of helminths. As has been shown for schistosomes, their surface is perfectly adapted to evade immune effector mechanisms. They are covered with a syncytial tegument that consists of an unusual double membrane complex with an apical plasma membrane and an overlying envelope (Hockley and McLaren 1973). The outer membrane is relatively fluid, ensuring a high lateral mobility of membrane lipids which favors repair after immune attack (Foley et al. 1986). The outer membrane of some stages can be replaced by shedding and incorporation of lipid compounds from tegumental storage vesicles (Kusel et al. 1975). Similar processes have also been observed for the infective larvae and adult worms of *Trichinella spiralis* (Philipp and Rumjaneck 1984) and other helminths (for a review, see Lightowlers and Rickard 1988).

Shortly after infection, the surface of schistosoma larvae is recognized by antiparasite antibodies and activates complement, although it gradually loses this antigenicity, acquiring a state of relative inertness. A part of this effect is ascribed to the incorporation of host molecules into the outer membrane of schistosomes, as a result of 'antigen disguise' (Terry and Smithers 1975). It was shown that schistosomes also incorporate membrane elements of the attacking neutrophils and other cells as well as lipids from host serum into their outer membrane (Pearce and Sher 1987). Indeed, MHC molecules, blood group glycolipids, fibronectin, and antibodies bound to the parasite surface by their Fc portion of host origin have all been detected. It was proposed that the outer schistosome membrane contains more host than parasite antigens (Saunders et al. 1987). This mechanism of antigen disguise seems to be employed also by other helminths, e.g. the surface of microfilariae of *W. bancrofti* contains host albumin as a major component (Maizels et al. 1984) and exposes blood group substances A and B (Ridley and Hedge 1977), whereas metacestodes of *E. granulosus* capture complement proteins from their host (Ferreira et al. 2000).

The fact that nematodes exhibit stage-specific patterns of surface antigens has also been interpreted in terms of immune evasion, e.g. the various larval stages of *Trichinella spiralis* have distinct sets of surface antigens (Philipp et al. 1980). It was suggested that antibodies induced by stage-specific surface antigens of an early larval stage do not recognize the surface of later stages. Each molt should thus provide an advantage, forcing the host to build up new and effective anti-surface antibodies. However, this concept was challenged by the finding that surface antigens crossreact between different stages and species of filariae, in spite of an apparent stage specificity as determined by molecular mass analysis (Maizels et al. 1983). Such shared antigenic determinants dominated the immune response, rendering the role of stage-specific antigens uncertain.

A further avoidance strategy consists of the production of a 'mucosal' glycocalix which serves as a surface coat to build a physical barrier between the worm surface and host effector mechanisms. Most probably, all helminths produce such mucous layers. Larvae of the nematode *Toxocara canis* produce a surface coat of about 10-nm thickness which surrounds the worm like a fuzzy envelope and is composed of mucins of different chain lengths that are secreted by the esophageal and secretory glands (Maizels et al. 2000). In vitro incubation of such larvae in immune sera leads to binding of antibodies that mediate the attachment of eosinophils. Subsequent shedding of the surface coat together with the bound eosinophils prevents intimate contact, and thus reduces the damage to the larvae (Badley et al. 1987). A similar shedding was also observed for juvenile stages of *Fasciola hepatica*. Larvae of this fluke are covered by a continuous layer of IgG after incubation in immune sera, and dispose of it by shedding and then replacing the glycocalix. This active process removes effector cells such as eosinophils and neutrophils and reduces the damaging effect of degranulation (Glauert et al. 1985).

Some helminths stimulate the host to produce layers of connective tissue, serving as a barrier that limits the access of immune cells, e.g. adult *Onchocerca volvulus* nematodes induce fibrous nodules in the skin (onchocercomas). Although the females are firmly embedded in these onchocercomas, the males probably move between nodules to inseminate the female worms (Schulz-Key and Karam 1986), and the microfilariae released by the female worms are also capable of leaving the nodule. The connective tissue of the nodule is infiltrated by neutrophils and eosinophils (Buttner et al. 1988). The influx of eosinophils seems to be triggered by the production of microfilariae by female worms (Wildenburg et al. 1996), whereas neutrophils are attracted by products of endobacteria living in symbiosis with the filarial nematodes (Brattig et al. 2001). In a comparable manner, the larval stages of some gut-dwelling nematodes induce the formation of tissues cysts, which may function to create a niche protected from immune effector mechanism. In infections with *Taenia solium* and *Echinococcus granulosus*, a connective tissue capsule with interspersed inflammatory cells surrounds the metacestodes, and the adults of *Paragonimus westermani* are located in cysts connected to the bronchial airways.

Blocking of complement and antibodies

Helminths can evade the consequences of complement-mediated damage through inhibition of complement action and through increased local consumption of complement factors. Moreover, they are able to inactivate antibodies and to induce the production of blocking antibodies.

Although antigens of many helminths activate the complement system, complement-dependent cytotoxicity is apparently restricted to the attrition of cestode oncospheres, which are destroyed by complement-fixing antibodies (Lightowlers and Gauci 2001). The activation of complement components by helminths without subsequent killing suggests the occurrence of mechanisms that inhibit the complement cascade. Indeed, a number of helminth complement inhibitors have been identified.

Young schistosomal larvae are highly susceptible to complement attack, but acquire resistance by several mechanisms within a few hours of penetrating their host. Shortly after infection, they express and probably secrete paracrystalline 'elongate bodies', which consist of the muscle protein paramyosin (Matsumoto et al. 1988). Through binding of C1q and inhibition of the binding of C4, paramyosin can prevent complement activation and thus protect the parasites (Laclette et al. 1992). In addition, a lipid-anchored 28-kDa protease on the surface of schistosome larvae can cleave C3 and C9 complement components and inhibit complement-mediated, neutrophil-dependent killing (Ghendler et al. 1996). Schistosomes also have a protease inhibitor with similarity to human CD59, which blocks the assembly of the membrane attack complex (Parizade et al. 1994).

Schistosomes and *Echinococcus granulosus* can use host-derived molecules for inactivating complement components. In the case of schistosomes, they incorporate the decay-accelerating factor (DAF) in their outer surface membrane or, in the latter case, 'factor H' in the wall of the cysts (Pearce et al. 1990; Ferreira et al. 2000). Both DAF and factor H inhibit the activation of the complement cascade downstream of the formation of the C3b–Bb complex.

Another way of knocking out disadvantageous complement effects is to 'stick' early complement factors to helminthic mucopolysaccharides. Such factors are found in the cystic bladder fluids of the tapeworm *Taenia taeniaeformis* (Hammerberg and Williams 1978).

Antibodies against surface proteins of helminths opsonize the parasites for recognition and effector activation by eosoinophils, neutrophils, and macrophages. Anti-

body degradation can therefore lead to the inhibition of these functions. Larvae of schistosomes and newly excysted juveniles of *Fasciola hepatica* secrete proteases that cleave IgG or IgE antibodies. As a consequence, the attachment of eosinophils to the worms is inhibited. The degradation products of the antibodies may serve for camouflage. Moreover, the peptides released during this process may downregulate macrophage activation (Auriault et al. 1981; Carmona et al. 1993; Pleass et al. 2000).

The skewing of immune responses after helminthic infections results in a shift of antibody classes and subclasses, which has profound effects on antibody-dependent effector mechanisms. Many helminths induce the production of high levels of IgG4 and IgE, parasite-specific IgG4 being present in much higher quantities compared with IgE, e.g. in filarial infections (Hussain and Ottesen 1986). The massive amounts of IgG4 are supposed to compete with IgE for epitopes, and may thus block otherwise occurring IgE-mediated cytotoxicity and allergic responses. In a similar way, IgG2 and IgM antibodies block anti-schistosomula granulocyte responses that depend on recognition of other isotypes for ADCC reactions. Furthermore, parasite-specific anti-helminth IgE antibodies occur together with unspecific IgE responses arising from the general elevation of IgE production. This effect would dilute parasite-specific IgEs on mast cells, and thus reduce allergic responses.

Inhibition of effector cell functions

Host effector cells are attracted to the site of infection by a variety of chemoattractants. To reach the parasites, the cells have to adhere to the vascular endothelial lining and to cross it by diapedesis. Helminths interfere with this process by various means. The hookworm *Necator americanus* secretes a protease which rapidly degrades the eosinophil-attracting chemokine eotaxin (Culley et al. 2000), and *Brugia malayi* microfilariae inhibit attraction of mononuclear cells and granulocytes by secretion of a serine protease inhibitor. In addition, this protease can inhibit granulocytic enzymes such as elastase and cathepsin G (Zang and Maizels 2001). The adhesion of granulocytes to vascular endothelial cells is inhibited by a glycoprotein from *Ancylostoma* and by eicosanoids from schistosomes (Nevhutalu et al. 1993; Moyle et al. 1994). Tissue-invading larvae of the lung fluke *Paragonimus westermani* inhibit eosinophils to degranulate and produce reactive oxygen species (ROS) through release of a cysteine protease (Shin et al. 2001) and mast cell degranulation is dampened by excretory/secretory (ES) products from adult *Schistosoma mansoni* worms (Mazingue et al. 1980).

Several species of intestinal nematodes secrete acetylcholinesterase, which can hydrolyze acetylcholine. In consequence, many proinflammatory functions of acetylcholine, such as release of granulocytic lysosomal enzymes, release of histamine, or other anaphylactogenic molecules by mast cells, are reduced and thereby may serve the 'well-being' of the nematodes (Lee 1996).

Defense against reactive oxygen species and detoxification

Activated macrophages, neutrophils, and eosinophils produce a variety of toxic products such as hydrogen peroxide, superoxide anion, and hydroxyl radicals, which are collectively termed ROS. ROS lead to protein oxidation, lipid peroxidation, depolymerization of polysaccharides, and DNA modifications, and thus has important antimicrobial functions. All aerobic organisms require mechanisms that protect cells against ROS produced during their own metabolism. Therefore, parasites have antioxidant enzymes such as superoxide dismutases, glutathione peroxidases, catalases, and peroxiredoxins, as components of their normal metabolism. Secretion of antioxidants by nematodes and their presence on or directly beneath the surface suggest, however, that helminths use antioxidants to block the products of the respiratory burst produced by immune cells (Henkle-Dührsen and Kampkotter 2001). Peroxiredoxins have been described from several filarial species and *Ascaris* spp., and it was shown that these proteins remove H_2O_2 and protect DNA from nicking by hydroxyl radicals in vitro. Glutathione peroxidases were identified as major soluble surface proteins of lymphatic filarial species and may function in the repair of oxidatively damaged membranes and the removal of H_2O_2 (Cookson et al. 1992). Catalases and superoxide dismutases have been described in a large number of nematodes and, although parasite-specific functions have been postulated, they have not yet been conclusively demonstrated (Henkle-Dührsen and Kampkotter 2001).

The glutathione *S*-transferases (GST) are a family of detoxification enzymes that catalyze the conjugation of reduced glutathione to xenobiotic and endogenous compounds. They are involved in the protection of tissues against oxidative damage by detoxification of lipid peroxidation products. Schistosomes have several isoforms of GSTs which are abundant in larval and adult worms. The enzymes are located in the subtegument, and at least transiently at or near the worm surface. Enzyme-blocking antibodies induced by experimental animal immunization with recombinant GSTs affect worm viability and fecundity after infection with *Schistosoma mansoni* or *S. japonicum* (Boulanger et al. 1991; Shuxian et al. 1997; Remoué et al. 2000). Studies in *Onchocerca volvulus* showed that this nematode also possesses and releases GSTs (Liebau et al. 1994) and immunization of cattle with GSTs from *Fasciola hepatica* induced protection against metacercarial infection (Morrison et al. 1996).

Inhibition of lymphocyte proliferation

Helminth infections often lead to diminished proliferation of antigen- or mitogen-stimulated lymphocytes. This reaction is the result of secreted products that can directly inhibit T or B cells, act indirectly through the induction of cytokine responses, or have combined activity.

Phosphorylcholine (PC) is a small component of phospholipids that occurs in a multitude of pathogens such as bacteria, trematodes, cestodes, and nematodes, but it is also present in the inner leaflet of vertebrate membranes. Nematodes are very rich in PC; part of the inhibitory activities of helminth culture supernatants is caused by this component. In-depth structural and functional studies on PC were performed with the rodent filaria *Acanthocheilonema viteae*. In vitro studies using the secreted PC-containing protein ES-62 revealed that the proliferation of activated B and T lymphocytes could be inhibited significantly (Harnett and Harnett 2001). The unresponsiveness of B lymphocytes is caused by PC-mediated uncoupling of the antigen receptor from intracellular proliferation signals such as the phosphoinositide-3-kinase and the Ras mitogen-activating protein kinase pathways (Deehan et al. 1998).

Another modulator of innate immune defenses found in many nematodes is the cysteine protease inhibitor cystatin. Recombinant cystatin from *Onchocerca volvulus* (onchocystatin) suppressed the proliferation of human T cells and the expression of MHC class II and CD86 molecules on monocytes. These findings are in line with studies on cystatins of *Brugia malayi* and of a rodent intestinal nematode that revealed an inhibition of class II MHC-restricted antigen processing (Dainichi et al. 2001; Manoury et al. 2001). At the same time, cystatin induced monocytes to produce enhanced levels of IL-10 and tumor necrosis factor α (TNF-α) and reduced amounts of IL-12 (Schonemeyer et al. 2001). These observations suggest that filarial cystatins shift the activities of macrophages toward an anti-inflammatory phenotype. In vivo studies in a rodent model confirmed the relevance of these observations, showing that application of filarial cystatin via osmotic pumps diminished the antigen-specific proliferation of spleen cells, whereas the antibody production was not suppressed (Pfaff et al. 2002). Not only are protease inhibitors found in nematodes; taenia cestodes secrete an inhibitor (taeniastatin) that is able to inhibit the production of IL-2 by T lymphocytes (Leid et al. 1986).

Immunomodulation by cytokine homologs

Helminths not only use molecules such as PC or protease inhibitors to alter the balance of the cytokine network, but also produce functional cytokine homologs that interact with the immune system. This information was initially gained by data mining of genome projects and represents a new aspect of the relationship between helminths and their hosts. For viruses, the strategy to produce mammalian cytokine or cytokine receptor homologs has long been known. The Epstein–Barr virus releases IL-10 homologs that account for a skewing of the cytokine balance towards Th2 responses (Liu et al. 1997) and the myxoma virus and other poxviruses encode for soluble IFN-γ receptors that bind and inactivate host IFN-γ (Upton et al. 1992; Alcami and Smith 1995).

To date there are two examples of helminth-produced cytokine-like molecules, but more of these proteins are likely to be discovered. A comparison of expressed sequence tags revealed that *Brugia malayi* has two genes with homology to macrophage migration inhibitory factor (MIF) (Pastrana et al. 1998). The gene of *B. malayi* MIF has an identity of 40–42 percent with vertebrate MIFs, and genomic homologs have been identified in *Onchocerca volvulus*, *Wuchereria bancrofti*, and also the free-living nematode *Caenorhabditis elegans*. In mammals this cytokine, secreted by T cells, macrophages, and eosinophils, induces macrophage kinesis and is associated with proinflammatory activities. Functionally, recombinant *B. malayi* MIF led to an upregulation of mediator production of macrophages with an ensuing marked eosinophil recruitment (Falcone et al. 2001). Thus, filarial MIF reveals an important link between macrophages and eosinophils during helminth infections. The MIF gene of *B. malayi* is transcribed in microfilariae and adult worms and is secreted in the vicinity of the worms, but it is also present in the hypodermis of adult worms and in the reproductive organs of females. Possibly, the continuous secretion of MIF induces a counterinflammatory phenotype of macrophages and contributes to the generation of 'alternately activated macrophages' that exert counterinflammatory activities (Loke et al. 2000).

In addition to MIF *B. malayi*, microfilariae and adult worms have genes to produce and secrete TGF-β-like proteins that bind to mammalian TGF-β receptors (Maizels et al. 2001). As TGF-β is involved in many downregulatory mechanisms, it is conceivable that this protein has a role in reducing inflammatory host responses.

OUTLOOK

In many areas of the world, individuals experience one or more parasitic infections. Despite considerable progress in controlling parasitic diseases, the threat to human health is increasing. Drug-resistant malaria has re-emerged as one of the most prevalent and dangerous diseases. Sleeping sickness is again epidemic in several countries in central and north-eastern Africa. Schistosomiasis cases do not decline despite available drug therapy.

Pathogens such as cryptosporidia or cyclospora are recognized increasingly as risk factors in food or water.

Understanding of the multiple effects of parasitic infections on the immune system is of increasing interest. Today there is no licensed vaccine for any human parasitic infection. This reflects the complexity of defining and directing of the correct protective immune response. Recent full-sequencing of the *P. falciparum* and *P. yoelii* genome, as well as ongoing efforts to sequence the genomes of *Trypanosoma brucei*, *T. cruzi*, *Toxoplasma gondii*, *Trichomonas vaginalis*, *Entamoeba histolytica*, *Schistosoma mansoni*, or *Brugia malayi*, provide the library from which vaccine candidates will be selected and creates considerable expectations for successful new vaccines. New technologies such as DNA immunization, expression library immunization, prime-boost regimens, or recombinant viruses will aid in the development and delivery of new vaccines. DNA-microarray technology will help to identify genes that are expressed at particular stages of the infectious process, at the site of both the parasite and the host. In vivo assays to induce or block the organ-specific expression of proteins will help to predict their contribution to immune control. In this context, it will be of prime importance to consider the immune escape mechanisms of protozoan and helminth parasites. Furthermore, parasites are a source of molecules with immunomodulatory activity, because evolution forged these parasites to become specialists in immunomodulation. Knowledge of the mechanisms of parasite immune evasion will thus add to our understanding of immune regulation in general and might at the same time provide concepts and molecules for the management of undesired immune responses.

Activation of humoral systems	3		

INTRODUCTION

Despite considerable advances in treating the primary causes of sepsis and shock, high rates of morbidity and mortality still remain associated with these conditions. The eradication of the septic focus, killing of invading microorganisms, and the support of blood circulation should allow a full recovery of the body's homeostasis. Unfortunately, this is not always achieved. Microorganisms and their products activate systemic host defense systems, which comprise both humoral (complement and coagulation cascade) and cellular components (monocyte/macrophage, neutrophils, and endothelial cells). Activated cells, in turn, release a vast array of mediators (cytokines, such as tumor necrosis factor (TNF) and interleukin 1 (IL-1), arachidonic acid metabolites, and nitric oxide) that amplify the inflammatory response. Circulatory failure, leading to inadequate oxygen supply to tissues, and direct cytotoxic effects of various mediators released in the course of the generalized inflammatory process may result. As a result of the extremely complex biochemical events that are involved in the pathophysiology of shock after severe sepsis, endogenous factors may contribute to prolongation and aggravation of the exogenous insult leading to a life-threatening autodestructive and selfsustaining perpetuation of inflammation.

DEFINITIONS

Many bacterial and nonbacterial factors may cause inflammation. Sepsis describes a systemic inflammatory response to a documented infection (Balk 2000). The local inflammatory process can cause an exaggerated systemic response, with inflammatory damage to otherwise healthy cells and organs distant to the primary site of the insult. For patients with such a deleterious systemic response without any detectable bacterial focus, the term systemic inflammatory response syndrome (SIRS) is used (Bone et al. 1992). Severe sepsis is sepsis associated with organ dysfunction, hypoperfusion, and hypotension. Multiple organ failure (MOF) has been defined as sequential failure of two or more organ systems in patients with clinical signs of sepsis (Baue 1975). Patients with severe sepsis and sepsis-induced hypotension despite adequate fluid resuscitation, along with the presence of perfusion abnormalities such as lactic acidosis, oligurea, or an acute alteration in mental status, are considered to be in septic shock. Sepsis and organ failure accompanied by (micro)circulatory failure can lead to impaired tissue oxygen supply and refractory shock. Septic shock refers to an acute event induced by bacteria and/or their products and is the most severe case of severe sepsis (Figure 1).

MEDIATORS OF IMMUNE REACTIONS

Sensing of pathogen-specific molecular patterns

In addition to microbial toxins and superantigens (which directly affect and modulate the hosts' immune response), a variety of constitutive microbial cell compo-

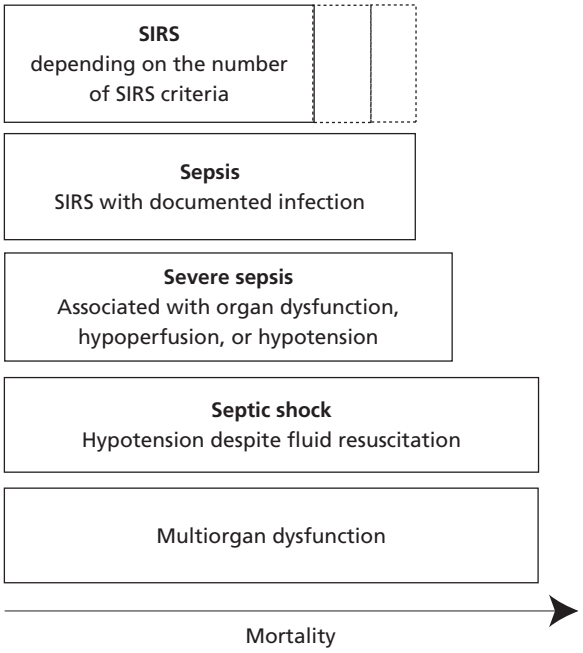

Figure 1 *Mortality in the systemic inflammatory response syndrome (SIRS). A progressively higher mortality of patients admitted to intensive care units can be observed as more severe inflammatory response criteria are met.*

nents induce inflammatory reactions. Although, for decades, studies concerning sepsis and shock dealt with gram-negative bacteria, infections with gram-positive bacteria, e.g. *Staphyloccus aureus* and enterococci, are recognized more and more to be of similar clinical relevance. The pathophysiological consequences of the systemic effects of infection are determined by a combination of factors derived from the infecting agent and responses of the host organism to the infection. Invading microorganisms such as bacteria, mycoplasmas, fungi, protozoa, or viruses and products thereof are immediately sensed by either serum proteins or membrane-bound proteins with predefined specificities. In recent years, a large number of so-called 'pathogen-specific pattern recognition molecules' have been described both as plasma components and as cell-surface receptors.

Characteristically, such pathogen-specific pattern recognition molecules specifically bind to repetitive carbohydrate structures on the surface of microorganisms or to an increasing number of defined molecules of microbial origin such as bacterial lipopolysaccharide (LPS), lipoteichoic acid (LTA), or bacterial DNA with cytidine phosphate-guanosine dinucleotide (CpG) motifs, now often referred to as pathogen-associated molecular patterns (PAMP) (Medzhitov and Janeway 1997).

Bacterial LPS, a constituent of the outer cell membrane of gram-negative bacteria, has been extensively studied for many years and represents the endotoxic principle of gram-negative bacteria (Rietschel et al. 1996). In the infected host, LPS is sensed by a specific LPS-binding protein (LBP) which in turn supports the interaction of LPS with either soluble or membrane-associated CD14. LPS-mediated cellular signaling, however, is dependent on a specific cell-surface receptor for LPS, now known as Toll-like receptor 4 (TLR-4) which cooperates with MD-2 (Beutler 2000; Alexander and Rietschel 2001; Heinrich et al. 2001) (Figure 2). TLR-4 signaling induces the release of proinflammatory mediators such as TNF (Jack et al. 1997) and initiates a pleiotropic cascade of events, including activation of the coagulation system, recruitment of phagocytes, and localization of the septic focus (Echtenacher et al. 1996). Similarly, LTA (which could be considered as a marker molecule of gram-positive bacteria) triggers the innate immune response using another member of the Toll-like receptor family, i.e. TLR-2, as a signal-transducing membrane receptor (Morath et al. 2002). Likewise, bacterial DNA containing immune stimulatory CpG motifs binds and signals through another member of the Toll-like receptor (TLR) family, i.e. TLR-9 (Krieg 2002).

ACTIVATION OF THE CELLULAR SYSTEM

Toll-like receptors

On the cell surface the Toll-like receptors (TLR) are crucial in transmitting the signal from structures commonly found on or in microorganisms (nonself) but absent on eukaryotic cells (self) into cells (Janeway 1992). A plethora of structures additional to LPS, LTA, and CpG are recognized by members of the TLR family including peptidoglycan (PGN), bacterial or mycobacterial lipoproteins, lipoarabinomannan, yeast cell wall components, or bacterial flagellin. By recognition of and response to a broad spectrum of diverse microbial patterns, the innate immune system orchestrates an inflammatory response to microbial invasion and triggers secretion and increased biosynthesis of key components in the inflammatory process. These genes include those encoding cytokines (TNF, interleukins IL-1, IL-6, and IL-12), chemokines (MIP-1α, IL-8), adhesion molecules, intercellular adhesion molecule 1 (ICAM-1), endothelial leukocyte adhesion molecule 1 (ELAM), inducible nitric oxide synthase (iNOS), and antimicrobial peptides, all of which contribute to the early host response against the invading pathogen (Jefferies and O'Neill 2002). The intracellular signaling cascade after activation of TLR-4 and TLR-2 is well characterized and uses common intracellular signaling intermediates MyD88, IRAK, and TRAF-6, resulting in activation of the nuclear factor κ B (NF-κB), mitogen-activated protein kinase (MAPK), and c-Jun N-terminal kinase (JNK) pathway activation which initiates the transcription of proinflammatory cytokines (Takeuchi and Akira 2001) (see Figure 2).

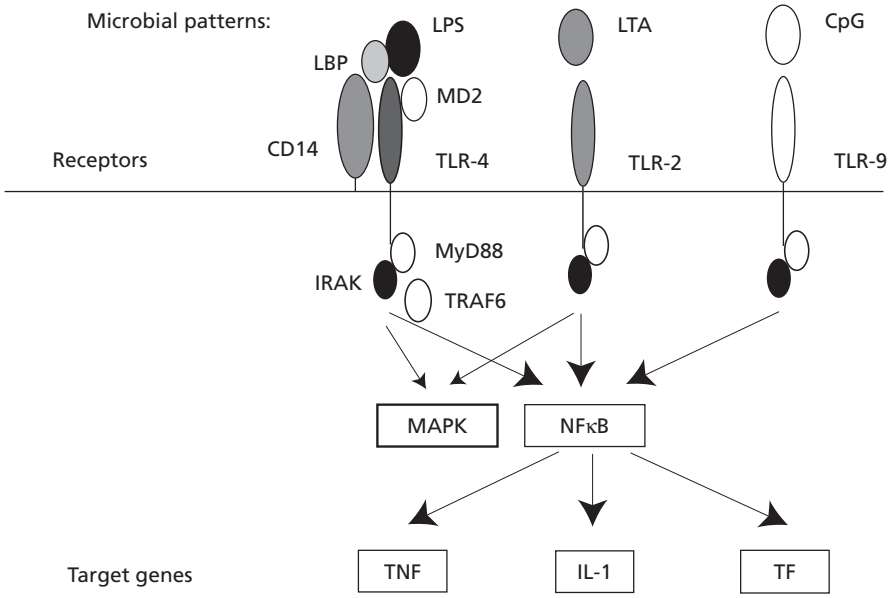

Figure 2 *The signaling pathway of Toll-like receptor 4 (TLR-4) after recognition of bacterial lipopolysaccharide (LPS) is mediated by LPS-binding protein (LBP), and CD14, TLR-4, and MD2. IRAK, IL-1 receptor-associated kinase; LTA, lipoteichoic acid; MAPK, mitogen-activated protein kinase; NF-κB, nuclear factor κ B; TNF, tumor necrosis factor; TRAF6, TNF receptor-associated factor 6; TF, tissue factor.*

Inflammatory cytokines

Among the proinflammatory cytokines, TNF and IL-1, are regarded as key players because their biosynthesis is quick and immensely efficient and their biological activities very powerful in starting off a cascade of additional proinflammatory mediators, e.g. via activation of NF-κB. TNF in particular appears to be the most potent mediator of the pathophysiology of the sepsis syndrome (Männel and Echtenacher 2000; Beutler 2002; Knuefermann et al. 2002). In combination with bacterial products or with IL-1, TNF rapidly leads to death with all symptoms of severe sepsis and shock in experimental settings (Okusawa et al. 1988a; Rothstein and Schreiber 1988; Waage and Espevik 1988). Effects on tissue metabolism, cardiac function, and vascular tone are three major mechanisms for the damage exerted by a concerted action of TNF with other mediators through the induction of effector molecules such as NO (Parrillo 1993). Serum TNF as well as IL-1 levels positively correlate with severity of infection (Calandra et al. 1990; Marks et al. 1990). Nuclear extracts from peripheral blood mononuclear cells from patients who succumbed to sepsis showed a significant increase in the nuclear binding activity of NF-κB compared with those of survivors. This supports the view that inflammatory cytokines such as TNF and IL-1 are central regulators of the inflammatory process in sepsis (Bohrer et al. 1997). Elevated levels of macrophage migration inhibitory factor (MIF) – yet another proinflammatory mediator that overrides the anti-inflammatory and immunosuppressive effects of glucocorticoids – can be detected in patients with severe sepsis and septic shock and enhanced survival is achieved by blocking MIF in experimental models of sepsis (Calandra et al. 2000). This gives further emphasis to the causal relationship of an exaggerated inflammatory immune status with sepsis and shock.

Although activation of cells of the innate immune system, e.g. macrophages for production of proinflammatory cytokines and antimicrobial molecules, is essential during the early phase of the infection, upregulation of costimulatory molecules and activation of dendritic cells leads to the instruction of the adaptive immune system. As professional antigen-presenting cells, dendritic cells bridge the gap between the innate and the adaptive immune response. Thus, TLRs can be considered as adjuvant receptors linking innate and adaptive immunity throughout the entire course of the host response to the infection (Kaisho and Akira 2002).

ACTIVATION OF HUMORAL SYSTEMS

Complement

The complement system is an integral part of the innate defense against infection and mediates many cellular and humoral interactions within the immune response, including chemotaxis, phagocytosis, and cell adhesion. Complement may be activated via three different routes: the classical pathway, the lectin pathway, and the alternative pathway (Figure 3). The classic activation pathway is initiated by immune complexes, whereas the lectin pathway and the alternative pathway activation

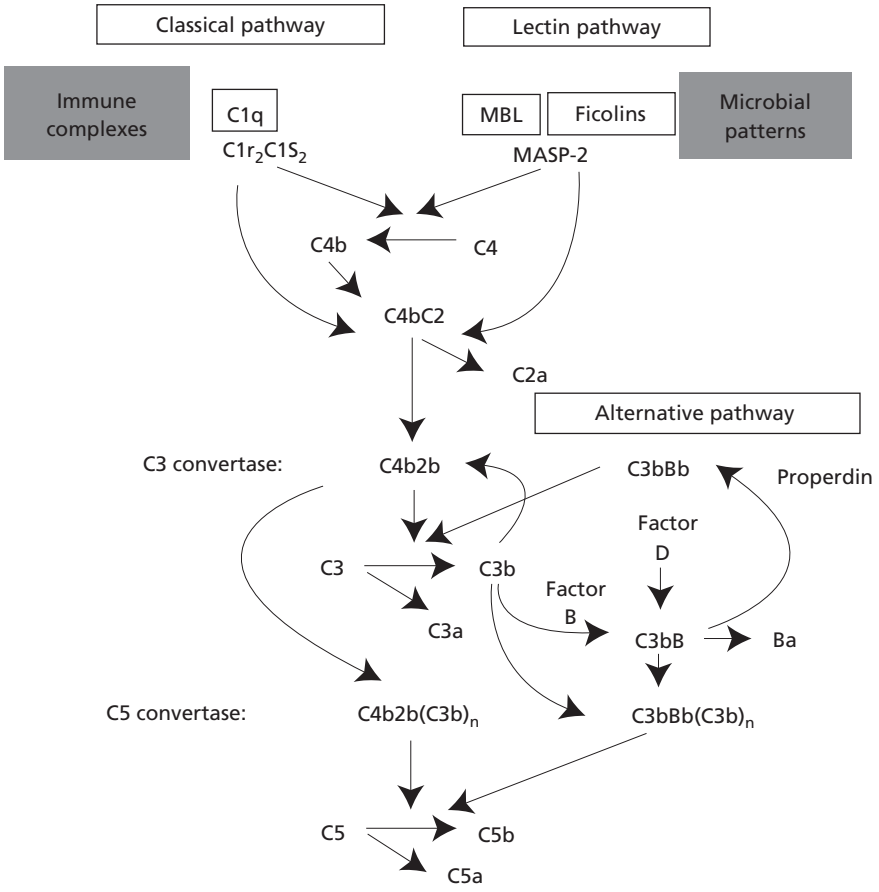

Figure 3 *The complement system is activated via the classic pathway initiated by immune complexes or via the lectin pathway initiated by pathogen-specific pattern recognition molecules such as the serum mannan-binding lectin (MBL) or ficolins leading to the activation of MBL-associated serine proteases (MASP). The alternate complement pathway stabilizes the C3 and C5 convertases, leading to generation of the anaphylatoxins C3a and C5a.*

can be initiated in the absence of immunoglobulins. Lectin pathway specific recognition molecules such as mannan-binding lectin (MBL) and the ficolins typically bind repetitive carbohydrate structures present on the surface of microbial organisms and translate this recognition into enzymatic activation of serine proteases associated with these recognition molecules (Neth et al. 2000; Petersen et al. 2001). The first PAMP recognition molecule identified to initiate the lectin pathway activation route of complement was the serum lectin MBL. Three lectin pathway-specific serine proteases have been identified so far and were termed MBL-associated serine proteases (MASP) (Thiel et al. 1997; Vorup-Jensen et al. 2000). As with MBL, ficolins were shown to form multimolecular serum complexes capable of activating complement after binding to microbial carbohydrate structures using MASP. MBL and the ficolins differ in their binding affinity to certain surface carbohydrate residues and thereby broaden the spectrum of potential triggers for lectin pathway activation.

Initiation of the lectin pathway activates the complement factors C4 and C2 to form C4b2b, a central enzymatic complex, which is able to cleave the abundant serum protein C3, thus generating C3 convertase which is common to both the classic and the lectin activation pathways of complement. As a result of complement activation pathway formation of the C3 and C5 convertases, the anaphylatoxins C3a and C5a are generated which increase plasma exudation and polymorphonuclear neutrophil chemotaxis.

The inherently labile C3 and C5 convertase complexes are stabilized by an amplification loop provided by the activation of the alternative complement pathway. A central component of this pathway is properdin; this is a positive regulator of complement activation and is rapidly released from polymorphonuclear neutrophils (PMN) in response to a variety of inflammatory stimuli such as LPS, TNF, or the anaphylatoxin C5a (Wirthmueller et al. 1997; Schwaeble and Reid 1999). Thus, in sites of inflammation where cytokines are secreted and complement is activated, secretion of properdin will amplify the complement cascade. A detailed discussion of the role of complement in infections is given in
Complement).

Inappropriate or excessive complement activation has been associated with septic shock. In plasma of patients

with sepsis, complement activation products, especially anaphylatoxins, can be found (Nakae et al. 1996). High concentrations of the anaphylatoxins C3a and C5a and terminal C5b–9 complement complexes seem to correlate with development of MOF and circulatory shock (Hack et al. 1989; Smedegard et al. 1989). Complement will directly promote procoagulant activity and indirectly induce cytokine production (Okusawa et al. 1988b; Scholz et al. 1990). The membrane-bound C5b–9 membrane attack complex and the anaphylatoxins induce tissue factor expression on endothelial cells and monocytes, thereby contributing to increased vascular permeability (Carson and Johnson 1990). Of the anaphylatoxins, C5a in particular is highly chemotactic for PMNs and induces the secretion of lysosomal enzymes from neutrophils and macrophages (Bengtsson et al. 1993). C5a seems to be a key mediator in inflammatory reactions, leading to vascular leakage by inducing TNF and endothelial P-selectin expression, and adhesion, migration, and aggregation of PMNs (Strachan et al. 2000). The receptor for C5a (C5aR) is found to be upregulated in sepsis on a variety of cells such as neutrophils, phagocytes, endothelial cells, and mast cells (Riedemann et al. 2002). Improved survival rates as well as attenuated inflammatory cytokine serum levels after blockade of the C5aR in sepsis models demonstrates the importance of the C5a receptor activation.

Coagulation

Activated humoral protease systems, i.e. coagulation, fibrinolysis, and the plasma kallikrein–kinin system, characterize severe infection and sepsis. Systemic activation of coagulation generates the deposition of fibrin in small blood vessels and microvascular thrombosis in critical organs, leading to organ failure. This occurs as consequence of the cellular activation during infection and of the release of inflammatory cytokines such as TNF and IL-1 (van der Poll et al. 1990). In addition, release of proteases from circulating cells has been suggested as an important factor in developing endothelial damage, leading to extensive permeability changes in various organs (Aasen and Buo 1993).

Tissue factor

A variety of mediators such as LPS and other bacterial products, various cytokines, among others particularly TNF, antigen–antibody complexes, and activated complement components are inducers of monocyte tissue factor (TF). Such mediators of inflammation as LPS, TNF, and IL-1 elicit concurrent changes in expression of leukocyte adhesion molecules on endothelial cells. Endothelial activation can be considered as a coordinated pathophysiological response to inflammation (Pober and Cotran 1990). The adherence of monocytes to P-selectin, an adhesion molecule expressed on the surface of activated platelets and endothelial cells, also induces TF expression. The transcription of the TF gene is mediated by both NF-κB and AP-1 sites located within the TF gene promoter (Mackman et al. 1991). During gram-negative sepsis circulating monocytes express significant levels of TF activity. TF is considered to be the primary triggering agent for the coagulation cascade and by far the most potent procoagulant substance known. Therefore, pathological expression of TF in monocytes and endothelial cells certainly contributes to the enhanced thrombogenesis in sepsis patients.

Platelets

Activated platelets that adhere and aggregate in large numbers at sites of vascular injury rapidly generate high local concentrations of thrombin (Morrissey and Drake 2002). Activation of platelets can also occur by complement components such as C5a and the C5b–9 complex (Rinder et al. 1995). Local activation of the coagulation cascade is immediately countered by anticoagulant systems such as the expression of thrombomodulin, antithrombin, production of TF pathway inhibitor, and protein C. Considering the prominent role of microvascular coagulation in sepsis and of activated protein C in hemostasis, antithrombotic and anticoagulant therapy seemed a reasonable attempt to prevent multiple organ dysfunction syndrome in severe sepsis (Aasen and Buo 1993).

Platelet-activating factor

Platelet-activating factor (PAF), a potent mediator implicated particularly in inflammatory conditions, is an alkylphospholipid produced by, and acting on, a variety of different cell types including PMNs, eosinophils, monocytes, macrophages, platelets, and endothelial cells (Ayala and Chaudry 1996). PAF is a potent chemotactic agent for neutrophils, inducing superoxide release, aggregation, and degranulation. Selfgenerating positive feedback cycles of PAF and various cytokines have become established. Synergistic effects of LPS and TNF with PAF on neutrophils may be crucial in initiating vascular damage in the very early phases of sepsis and shock. Impairment and retraction of endothelial cells by PAF has been observed in experimental systems in vitro.

CIRCULATORY FAILURE AND DIRECT CYTOTOXIC EFFECTS

A new understanding of sepsis pathophysiology has emerged, focused on the tight interplay and coupling of inflammation, microvascular coagulation, and endothelial cell dysfunction (Joyce and Grinnell 2002). In the early events leading to severe sepsis, the host response results in the activation of a number of systems aimed at

ridding the host of the infection. After activation of the humoral systems, i.e. the complement cascades, coagulation, fibrinolysis, and the kallikrein–kinin system, cells such as neutrophils, platelets, and mast cells also become involved. Circulating neutrophilic leukocytes are activated and adhere to the endothelium of the blood vessels. Such margination of PMNs and leukostasis provoke massive release of proteases, radicals, and phospholipid derivatives. Infiltrating neutrophils trigger the release of a second wave of chemoattractants/cytokines which amplify the recruitment of additional phagocytes. Margination and activation of neutrophils as a result of the action of inflammatory cytokines can trigger pulmonary vascular endothelial injury and lead to the adult respiratory distress syndrome (ARDS). Sequestration of activated leukocytes may also affect the intestine, leading to translocation of bacteria, and their toxins, leading to further recruitment and activation of monocytes/macrophages, neutrophils, and endothelial cells, respectively.

Microcirculation

The activation of the humoral and cellular inflammatory systems affects the endothelial barrier function and vasoregulation and leads to sepsis-induced dysregulation of the microcirculation at the level of resistance arterioles, nutritional capillary perfusion, and/or postcapillary venules (Lehr et al. 2000). The microcirculation constitutes a functionally highly active system which dynamically interacts with circulatory and tissue-associated cells such as leukocytes, platelets, neutrophils, and mast cells, produces mediators, and contributes to the regulation of the vascular tone. Consequences of microcirculatory dysfunction are the breakdown of endothelial and epithelial barrier function, vasodysregulation, and disturbance of oxygen transport.

A characteristic of septic (hyperdynamic) shock is the increased cardiac output and the loss of peripheral resistance resulting in increased transport of blood into the periphery (Lehr et al. 2000). With the inadequate peripheral resistance which is probably caused by sepsis-induced overproduction of NO and the resultant massive peripheral vasodilatation, the cardiac output is redistributed with compensatory hypoperfusion of visceral organs.

As a consequence of leukocyte activation in sepsis and disseminated intravascular coagulation (DIC) the microcirculation becomes overburdened with inflammatory cells. Endothelial cell swelling, leukocyte sequestration, and microthrombus formation are signs of endothelial cell activation and characterize the state of microcirculation in sepsis. In agreement with clinical observations in septic patients, sequestration of activated leukocytes has been shown to contribute to subsequent tissue injury in animal models.

Neutrophils, macrophages, and other phagocytic cells are capable of generating large amounts of highly toxic molecules such as reactive oxygen intermediates and reactive nitrogen intermediates (Bogdan et al. 2000). Besides their antimicrobial activity, these reactive intermediates are powerful immunoregulators. By inhibition of lymphocyte proliferation they may also serve to control inflammatory processes and to account for the immunosuppressed state in certain infections. Important signaling pathways regulating cytokine production and responses, cell survival, and tissue damage are influenced by reactive oxygen and nitrogen intermediates.

Tissue damage, and in particular endothelial cell damage mediated by free radical production, seems to be of considerable importance in sepsis and shock. The crucial cells for free radical production are PMNs (Nussler et al. 1999). In the inflammatory environment these cells become recruited and activated, and they adhere to the endothelial surface and release lysosomal proteases as described above. Activated neutrophils also produce superoxide by undergoing a respiratory burst. Superoxide is rapidly converted to hydrogen peroxide and toxic free radicals which can damage the endothelium (Ayala and Chaudry 1996). Endothelial membrane injury then leads to increased vascular permeability.

Septic shock is characterized by hypotension, vascular collapse, and multiorgan dysfunction. In sepsis, cardiac dysfunction and altered vascular tone, the loss of vascular homeostasis, and diffuse endothelial cell injury all increase microvascular permeability and favor the development of zones of ischemia. NO released by endothelial cells is a major endogenous arteriolar vasodilator. Thus, the large amounts of NO produced in the vascular wall by the cytokine-inducible NO synthase is considered to play an important role in septic shock (Li and Forstermann 2000). As with many important mediators of the host response to infection, the multifaceted actions of NO generate a picture of beneficial as well as detrimental effects. NO has both anti-inflammatory and proinflammatory properties depending on the type and phase of the inflammatory reaction. NO has a vasoprotective function by inhibiting platelet aggregation and adhesion to the cell wall, thus activating antithrombotic and anti-inflammatory effects by downregulation of NF-κB activation. However, NO is proadhesive for PMNs and can also be seen as an indirect toxic effector substance via the formation of reactive nitrogen species or as a mitochondrial inhibitor (Feihl et al. 2001). A correlation between NO-induced mitochondrial dysfunction and the severity and outcome of septic shock suggested that bioenergetic failure could be an important pathophysiological mechanism for MOF (Brealey et al. 2002).

Endothelial cell damage

The endothelial interface plays a central role in coordinating the microcirculatory system and promoting tissue perfusion and oxygen supply. Endothelial cells serve a

number of metabolic and regulatory functions, e.g. production of vasoactive compounds such as prostacyclin, thromboxane, and NO, control of hemostasis, blood coagulation, and fibrinolysis, platelet and leukocyte interactions with the vessel wall, and regulation of the vascular tone and blood pressure. The release of inflammatory mediators such as TNF in the early phase of sepsis initiates endothelial cell-surface activation affecting a number of pathways, e.g. oxidation, adhesion, cytokine release, apoptosis, and NO production. In addition, TNF production contributes to further inflammation through thrombin-induced activation of endothelial cells, platelets, and vascular smooth muscle. These responses can directly damage the vascular endothelium by inducing enhanced microvascular coagulation, endothelial dysfunction, and apoptosis of endothelial cells. However, so far there are no data documenting any role for endothelial cell apoptosis in the pathogenesis of sepsis (Hotchkiss et al. 2002).

As a result of DIC and microvascular thrombosis, decreased tissue perfusion, and hypoxemia organ dysfunction, organ failure, and shock can ensue (Figure 4). Therefore, endothelial dysfunction resulting from the cascades of successive activation events is considered to play a central role in modulating the tightly linked and interdependent inflammatory and thrombotic responses that characterize the pathophysiology of systemic inflammation. In patients, various markers for an activated endothelium such as ICAM, vascular cell adhesion molecule (VCAM), and E-selectin are found to correlate with the severity of sepsis (Reinhart et al. 2002). The breakdown of normal vascular homeostasis, combined with depressed myocardial function, alterations in peripheral vasculature, and failure of oxygen exchange, will finally lead to tissue hypoxia and organ failure.

IMPLICATIONS FOR THERAPIES

An infectious insult results in stimulation of the immune system. This response is normally advantageous, but, when uncontrolled or excessive, it becomes deleterious for the host. This is the situation in septic shock.

Management of coagulopathy

The importance of the coagulation system resulting in, and exacerbating, the blockade of microvascular flow, and thus tissue oxygenation in sepsis, has suggested antithrombotic strategies as promising therapeutic approaches. A number of clinical sepsis trials with antithrombin or tissue factor pathway inhibitor have, however, shown that correcting the coagulation defect alone in sepsis was not sufficient to prevent mortality. Besides prevention of DIC by antithrombotic treatment, e.g. with activated protein C, it also seemed important to inhibit the thrombin-induced proinflammatory effects such as activation of platelets and endothelial cells,

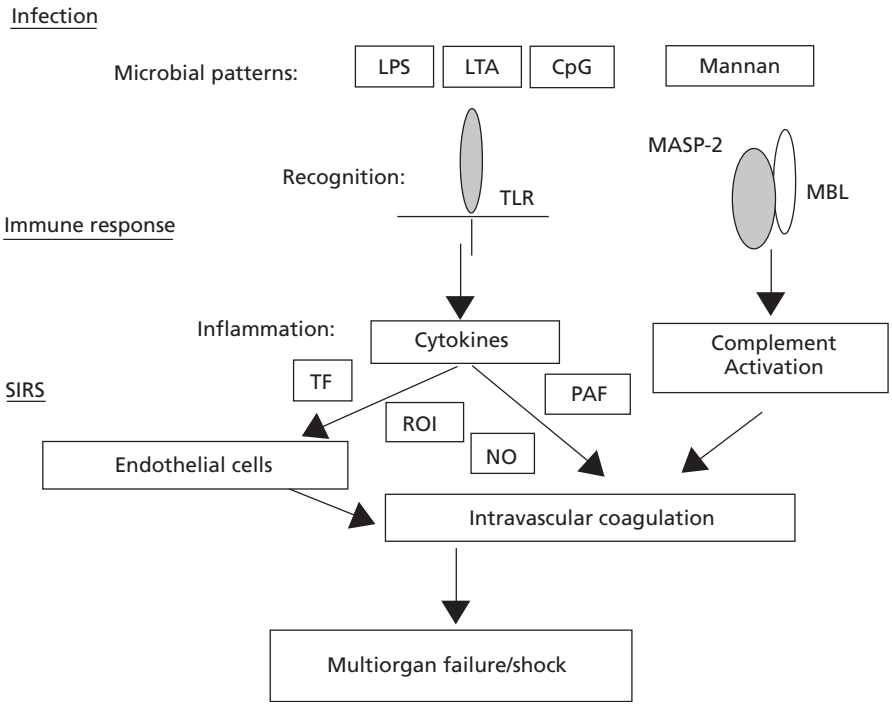

Figure 4 *Schematic overview of the pathogenesis of the systemic inflammatory response syndrome (SIRS) developing after infection and leading to severe sepsis and shock. LPS, lipopolysaccharide; LTA, lipoteichoic acid; MASP, MBL-associated serine protease; MBL, mannan-binding lectin; NO, nitric oxide; PAF, platelet-activating factor; ROI, reactive oxygen intermediates; TLR, Toll-like receptor; TF, tissue factor.*

NF-κB-dependent cytokine production, and adhesion molecule expression (Bernard et al. 2001). In addition, direct thrombin-independent anti-inflammatory effects of activated protein C, such as reduced NF-κB-dependent gene activation, may also result in protection of endothelial cells from apoptosis and promote cell survival and therefore may be important in restoring endothelial and mononuclear cell function.

Counterregulation of inflammation

The immune system has evolved potent anti-inflammatory programs to terminate and counterbalance inflammation because homeostasis requires compensatory mechanisms to maintain the internal milieu. A number of anti-inflammatory mediators such as IL-4, IL-10, IL-13, TGF-β, soluble TNF receptors, and IL-1 receptor antagonist are released for downregulating the immune response. In addition to these extracellular molecules, the integral nature of apoptosis provides a means of regulation of immune responses at the cellular level (Mahidhara and Billiar 2000). Delayed apoptosis of neutrophils (correlating with an upregulated inflammatory response), as well as increased lymphocyte apoptosis (possibly implicating immunosuppression), have been observed in patients with severe sepsis.

Endogenous corticosteroids downregulating the inflammatory response play a very important role in infections in general and are essential for the host to survive septic shock. Apart from modulating the immune system, corticosteroids have an important role in modulation of blood pressure and expression of adrenergic receptors. Steroid use in septic shock makes some sense but has conflicting support in the literature (Ritacca et al. 2002). A beneficial effect of corticosteroids in the treatment of sepsis may be a matter of dose, timing, duration of treatment, and patient selection (Spijkstra and Girbes 2000). The observations of beneficial effects of corticosteroids at doses that are close to the levels measured in stress situations support the idea of endocrine effects influencing the inflammatory responses in sepsis.

The theory of uncontrolled inflammation ultimately causing system-wide effects, shock, and end-organ failure, and the understanding of the importance of counterregulation lead to many therapeutic strategies aimed at blocking the early mediators of the proinflammatory response in sepsis. Among others, neutralization of bacterial products (LPS), inhibition of neutrophil recruitment, priming and activation by inhibition of chemoattractants (C3a, C5a), neutralization of chemokines, inhibition of rolling (selectin mediated), sticking (integrin mediated), and adherence, modulation of inflammatory mediators (C5a, TNF, IL-1, MIF, PAF), blockade of NO, arachidonic metabolites, reactive oxygen metabolites, and interference with signal transduction (NF-κB) activity have been tried in many experimental as well as clinical settings. Even though data from good animal models have conclusively demonstrated the importance of these mediators in the pathogenesis of the dysregulation in septic shock, the results of anti-inflammatory therapeutic strategies in the clinic were disappointing.

However, one has to keep in mind that the imminent problem in sepsis therapy is based on the fact that as yet no good parameters are available to evaluate the immunological status of the patients. After infection, patients go through an early inflammatory phase characterized by immediate responses of the innate immune system. In addition to the innate immune response, the adaptive immune response is recruited via, among others, activation of dendritic cells. This activation of the immune system provokes a counterregulatory anti-inflammatory or hypoinflammatory phase. For some time an overlap of the hyperinflammatory and hypoinflammatory phases may be present in the same infected organism, depending on the type of infection and the cell type, organ, or location under investigation. Although at the same time the presence of inflammatory mediators is required for antimicrobial action, anti-inflammatory mechanisms are essential for protection of tissue and organs. In such situations, the application of granulocyte colony-stimulating factor (G-CSF) might be a solution because transiently activated PMNs will be recruited with potent antimicrobial activity and – by an unknown mechanism – G-CSF acts in an anti-inflammatory manner (Boneberg and Hartung 2002).

There are some indications that careful patient stratification based on immunological characteristics that determine the timing for intervention might improve the outcome, as illustrated in the sepsis trial with TNF inhibition (Abraham et al. 1997; Grau and Männel 1997). As global tissue hypoxia is a key development preceding MOF and death, early goal-oriented manipulations of cardiac overload, afterload, and contractility to achieve balance between systemic oxygen delivery and oxygen demand seems to be a more definitive and effective resuscitation strategy (Rivers et al. 2001).

At least of equal importance is the notion that microcirculatory dysfunction during sepsis is not the consequence of one single mediator but of complex cascades of mediator systems, with these mediators having a striking redundancy in their modes of action. Evidently, inhibition of one mediator, even if it is an important one, might not be sufficient to get the dysregulated system back to homeostasis (Lehr et al. 2000). This is suggested by the relatively successful clinical trial with activated protein C where antithrombotic and anti-inflammatory effects are combined (Bernard et al. 2001). The combination of the divergent as well as the redundant effects of the different mediators, the difficulty of obtaining clear parameters to determine the immune status of the patient, as well as the detrimental synergistic positive feedback actions of the inflammatory

pathways involved, will continue to make it extremely difficult to find a successful and safe therapeutic strategy for severe sepsis and shock.

INTRODUCTION

A number of microorganisms have the capacity to remain viable within the host although the latter mounts an adequate immune response against them. This gives rise to a T-cell-mediated chronic inflammatory response aimed at restraining the harmful effects of the persisting microorganism. This response follows a characteristic pathophysiological pattern (granuloma formation) and often entails significant tissue damage in the form of necrosis or fibrosis. A major driving force in current inflammation research is the molecular dissociation of protection and pathology associated with this type of chronic inflammatory response. It remains a challenging therapeutic goal to manipulate, at will, the pathological sequelae of inflammation without impairing antimicrobially active immune defenses expressed concomitantly. This chapter outlines the salient features of immunopathology associated with T-cell-mediated delayed-type hypersensitivity (DTH) and discusses some strategies to prevent them.

DELAYED-TYPE HYPERSENSITIVITY

Definition

Delayed-type hypersensitivity is a highly dynamic, T-cell-mediated inflammatory response to persisting antigen. It is a typical immunological reaction to a variety of facultative intracellular bacteria, fungi, and parasites (Table 1) (Zumla and James 1996). Contact sensitivity to some chemical agents, experimental allergic encephalomyelitis, and graft rejection are other prototypes of DTH reactions induced by nonmicrobial stimuli.

The best known example of a DTH reaction is the response of a sensitized individual to intradermal injection of a purified protein derivative (PPD) of the causative agent of tuberculosis, *Mycobacterium tuberculosis*. The DTH reaction to PPD starts with reddening and induration at the site of antigen deposition after about 12 h. This delayed reaction peaks after 48–72 h and slowly wanes thereafter (Figure 1). Morphologically, the DTH skin reaction is characterized by the perivascular accumulation of predominantly mononuclear cells in the subcutaneous tissue and dermis. The majority of infiltrating lymphocytes are of the $CD4^+$ subtype. Over time, activated monocytes differentiate into epithelioid macrophages. As microvascular permeability is also increased, there is dermal edema and deposition of fibrin in the interstitium. The induration characteristic of a skin DTH reaction is a consequence of both the persistent infiltration of mononuclear cells and a limited amount of inflammatory fibrosis.

DTH and granuloma formation

Granulomas are defined as focal accumulations of mononuclear cells in response to a chronic antigenic

stimulus. Thus, the skin DTH reaction may alternatively be termed a 'mini-granuloma' of the skin. Vice versa, antigen-specific granulomas in visceral organs in most instances fulfill all criteria of a DTH reaction and may therefore be viewed simply as tissue correlates of a DTH reaction.

Histopathologically, granulomas are characterized by aggregates of epithelioid cells with indistinct cell boundaries, which often seem to fuse into one another. The nucleus of activated macrophages is less dense than that of the surrounding lymphocytes ($CD4^+$, $CD8^+$ T cells and B cells), is oval or elongate ('shoe imprint' morphology), and has prominent nucleoli (Figure 2). Older granulomas are surrounded by a collar of fibroblasts and connective tissue, e.g. collagen fibers. Depending on the eliciting microorganism, neutrophil and eosinophil granulocytes are also present. Frequently, epithelioid cells fuse to form multinucleated giant cells, which may become as large as 50 μm in diameter, and show either an ordered peripheral arrangement of nuclei (Langhans-type giant cell; Figure 2) or a haphazard distribution of nuclei (foreign body-type giant cell).

In contrast to foreign body granulomas, which occur independently of T cells and are characterized by little cellular turnover, T-cell-mediated (DTH-type) granulomas are highly dynamic: in addition to local proliferation of T cells, new mononuclear cells are constantly recruited into the lesion by virtue of mediators secreted by activated, antigen-specific T cells.

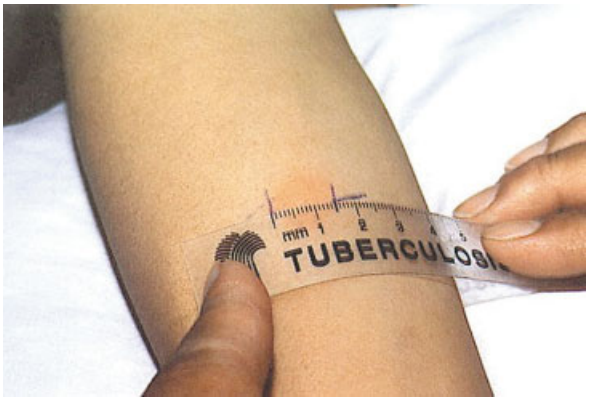

Figure 1 *Delayed-type hypersensitivity skin reaction to intracutaneous injection of purified protein derivative of* Mycobacterium tuberculosis*. Within 48–72 h, a positive tuberculosis (TB) skin test is marked by an area of reddish induration greater than 10 mm. It is the palpable induration that determines the size, not the area of redness. Mechanisms of granulomatous inflammation

In the course of a primary immune response, $CD4^+$ cells are sensitized to digested antigen presented in the context of major histocompatibility complex (MHC) class II and appropriate costimulatory molecules, such as CD80 or CD86 on the surface of antigen-presenting cells, e.g. dendritic cells (Jankovic et al. 2001). The nature of the cytokine environment present during this priming phase ultimately determines the differentiation of the $CD4^+$ effector cell subtype: the presence of interleukin (IL) 12 and interferon γ (IFN-γ) will promote the development of T-helper (Th) 1 cells, which are capable of secreting IL-2, IFN-γ, and lymphotoxin α (LT-α), whereas the predominance of IL-4 and IL-10 will favor the differentiation of Th2 cells which preferentially produce IL-4, IL-5, IL-6, IL-9, IL-10, and IL-13 (Chtanova and Mackay 2001). Some of these differentiated cells will become long-lived memory cells. Antigen-specific effector and memory T cells recirculate in the bloodstream and can enter sites of antigen deposition where they subsequently produce cytokines for further amplification of the type 1 and 2 immune reaction patterns, respectively.

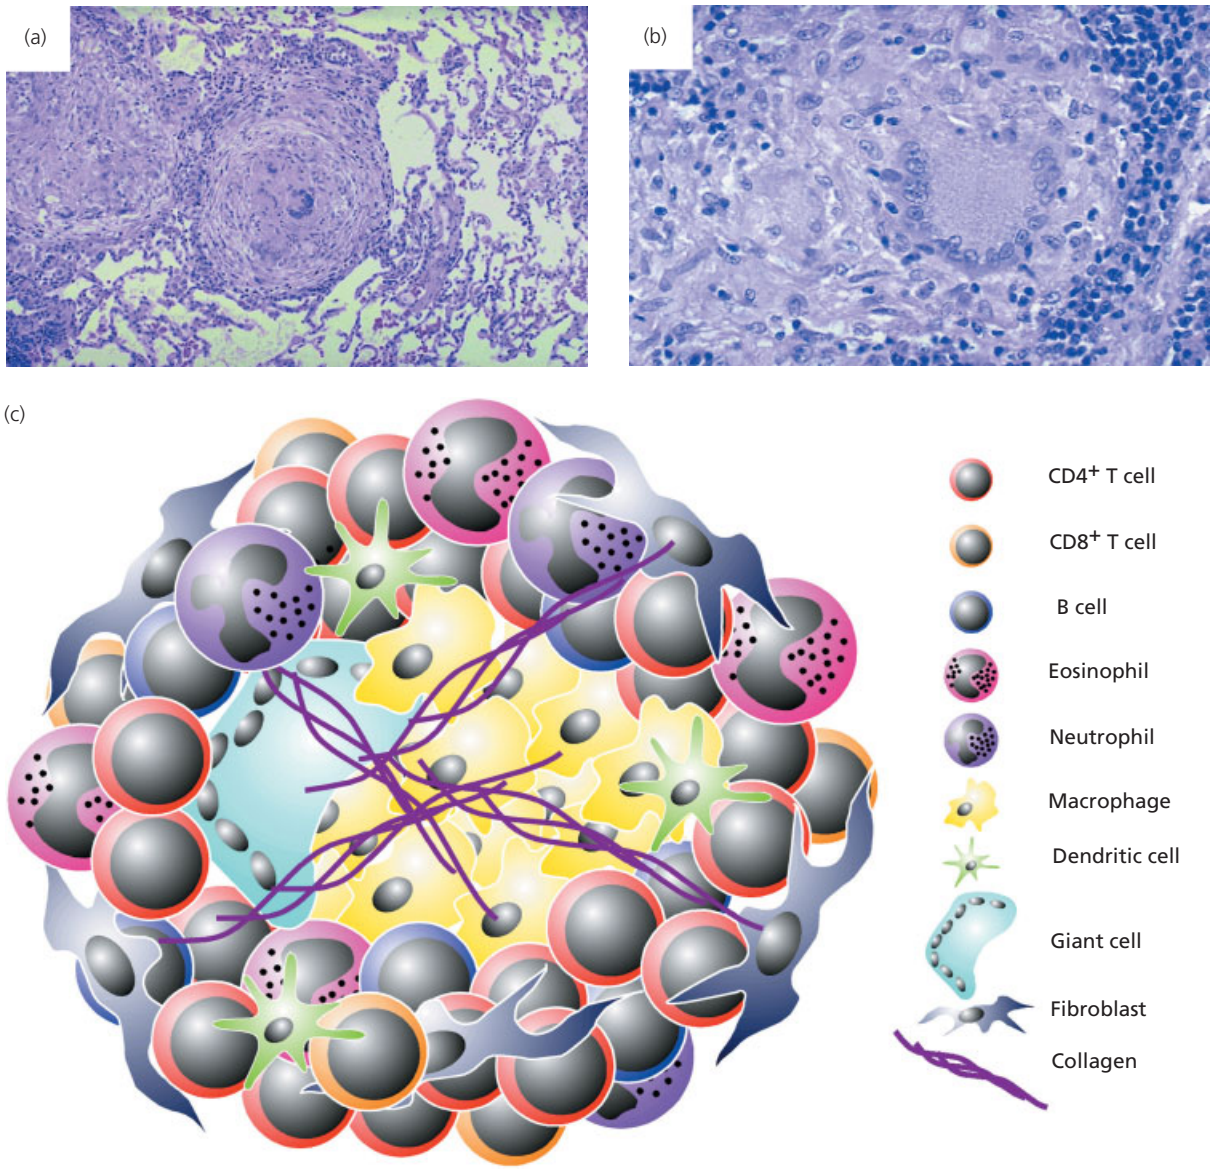

Figure 2 *Granulomatous inflammation:* **(a)** *medium power microscopic view of two pulmonary granulomas with giant cells;* **(b)** *high power microscopic view of well-structured granuloma with epithelioid macrophages and Langhans giant cell; and* **(c)** *schematic drawing of cells organized within the granuloma structure. The recruitment of effector $CD4^+$ cells into inflammatory lesions requires interaction with adhesion molecules as well as the sensing of a gradient of chemoattractant molecules by specific receptors. The course of events is initiated by activated complement components (e.g. C5a), vasoactive amines, bradykinin, leukotriene B_4, platelet-activating factor, and small amounts of IL-1 and tumor necrosis factor (TNF) produced at the site of insult. The last two cytokines upregulate the expression and increase the avidity of selectin and integrin receptors on the surface of the endothelium, thereby facilitating extravasation of leukocytes from the bloodstream (Shikama et al. 1989; Issekutz 1993a,b; Lukacs et al. 1994b).

To produce a manifest DTH, further amplification of this initial inflammatory reaction is necessary. The subsequent quality of the DTH response therefore largely depends on the cytokines produced by the $CD4^+$ effector cells of either Th1 or Th2 subtype initially recruited to the lesion, and the chemokine cascade that they initiate. It is convenient at this point to distinguish between type 1 and type 2 DTH and granuloma formation, depending on the T-helper cell subset mediating the monocytic inflammation. Although for the most part this chapter summarizes data obtained from in vivo infection models, many of the results reviewed in this section are based on an in vivo model of hypersensitivity granuloma elicitation in which presensitized mice are

challenged with beads coated with PPD of *Mycobacterium bovis* (Th1-induced type 1 granulomas) or soluble *Schistosoma mansoni* egg antigens (Th2-induced type 2 granulomas) (Kunkel et al. 1996, 1998).

T-helper 1 cells secrete copious quantities of TNF and IFN-γ capable of attracting additional monocytes and T cells into the lesions, mostly by increasing the binding of these cells to inflamed endothelium (Springer 1994). In particular, TNF and IFN-γ were shown to upregulate intercellular adhesion molecule (ICAM) expression on endothelial cells (Lukacs et al. 1994b), a molecule expressing binding sites for lymphocyte function-associated antigen 1 (LFA-1) (present on lymphocytes) and for complement receptor 3 (present on monocytes). The essential role of TNF and IFN-γ for granuloma initiation and maintenance has been amply demonstrated in many models of infection in which neutralization of TNF and IFN-γ effectively abrogates granuloma formation, or converts it to a Th2 pattern with increased eosinophil infiltration and fibrotic degeneration (Kindler et al. 1989; Amiri et al. 1992; Mastroeni et al. 1992; Joseph and Boros 1993; Chensue et al. 1997b; Smith et al. 1997). The injection of IFN-γ alone is able to induce a lymphocytic and monocytic infiltration (Nathan et al. 1986; Issekutz and Issekutz 1993), and TNF and IFN-γ act synergistically in this respect.

Lymphotoxin (LT), another member of the TNF superfamily synthesized by activated lymphocytes, occurs in a homotrimeric form ($LT\alpha_3$) or a heterotrimeric form ($LT\alpha_1\beta_2$), the latter being membrane bound. While the heterotrimer is probably involved in the direct activation of macrophages (Ehlers et al. 2003), $LT\alpha_3$ is necessary for establishing the proper architecture of the granuloma, because, in the absence of $LT\alpha_3$, T cells do not migrate into the granulomatous lesion, but only accumulate in perivascular cuffs (Roach et al. 2001).

The structural organization of type 1 granulomas involves elaboration of specific chemokines and induction of specific chemokine receptors on target cells. TNF and $LT\alpha_3$ orchestrate the early induction of chemokines necessary for initial leukocyte recruitment and thus facilitate granuloma initiation (Roach et al. 2001, 2002), e.g. TNF and lymphotoxins are major inducers of the chemokine CCL5, and IFN-γ and TNF synergize in eliciting CCL5 from endothelial cells (Marfaing-Koka et al. 1995). CCL5 attracts activated or memory Th1 cells, bearing the cognate receptor CCR5, into inflammatory lesions. IFN-γ induces the chemokines CXCL9, CXCL10, and CXCL11, which in turn attract effector Th1 cells bearing the common receptor for these chemokines, CXCR3 (Matsukawa et al. 2001). When newly recruited monocytes become activated and differentiate into epithelioid cells, they are also capable of secreting chemokines, e.g. CCL2, that further attract and activate monocytes (Matsushima et al. 1988; Zachariae et al. 1990). Therefore, when the receptor for CCL2 (CCR2) is absent, type-1 granuloma formation is impaired (Boring et al. 1997). Multinucleated giant cells probably also participate in amplifying the type 1 granulomatous response, because transcripts for TNF, IL-1β, IL-6 were detected in single cells generated in vitro (Seitzer et al. 1997) or analyzed in vivo (Myatt et al. 1994).

Nitric oxide (NO) is probably involved in the termination of the Th1 granulomatous response: NO, produced by the IFN-γ-inducible enzyme nitric oxide synthase (2NOS-2), inhibits type 1 granuloma size and cellularity, particularly with respect to eosinophils and neutrophils, by modulating chemokine (CCL2, CCL3, CXCL10) as well as TNF and IFN-γ expression (Hogaboam et al. 1997; Ehlers et al. 1999).

T-helper 2 cells orchestrate the development of a different kind of granuloma. IL-4 leads to a significant increase in cellularity, size, procollagen type III expression, and accumulation of eosinophils (even in preexisting Th1 granulomas). In addition, endothelial cells may become activated by IL-4 and secrete CCL7 which also induces the recruitment of eosinophils (Shang et al. 2002). IL-4, in the presence of TNF, can induce CCL2 and CCR2 expression in fibroblasts. CCL2 is involved in fibrosis through the regulation of profibrotic cytokines, e.g. transforming growth factor β (TGF-β), and the generation and deposition of a collagen matrix (Hogaboam et al. 1999). Fibroblasts from type 2 granulomas generate more CCL2 than Th1 fibroblasts. Generally speaking, CCL2, CCL7, and CCL8 are more involved in type 2 than in type 1 inflammation (Chensue et al. 1996; Qiu et al. 2001). Likewise, CCL11 (eotaxin) and CCR3 (eotaxin receptor) levels are higher in Th2 than in Th1 granulomas. CCR8 (the receptor for CCL1, CCL4, and CCL17 also found predominantly in type 2 granulomas) is exclusively expressed on Th2 cells and contributes to a functional Th2 granuloma, because, in its absence, there is impaired IL-5 production and eosinophil recruitment (Chensue et al. 2001).

Whereas NOS-2 dominates Th1 immune reactions, arginase is predominantly expressed in Th2 responses and is responsible for fibrosis in type 2 granulomas (Hesse et al. 2001). Arginase production is mediated by IL-13 and regulated by substrate depletion through Th1-induced NOS-2 activity (Rutschman et al. 2001).

It is already obvious from the above that there is extensive opportunity for crossregulation between these two pathways of granuloma formation (Matsukawa et al. 2001), e.g. Th2 cells may – via the secretion of IL-10, IL-4, and IL-13 – effectively diminish a Th1 response by downregulating IL-12, IFN-γ, TNF, and chemokine production in Th1 cells (Ruth et al. 2000). In contrast, the type 1 cytokine IL-12 dramatically reduces type 2 lesion size, primarily curtailing eosinophil recruitment (Chensue et al. 1997a). In the absence of IL-4, type 1 inflammation is exacerbated, but an established Th2 granuloma will not convert to a Th1 granuloma, because persistent expression of IL-13, IL-5, and CCL7 can compensate for the defect (Chensue et al. 1997a). CCL5 promotes the Th1

response and mediates crossregulatory inhibition of type 2 granulomas (Chensue et al. 1999). However, chemokines influence granuloma formation not only through a direct effect on leukocyte chemotaxis, but also through altering the Th1/Th2 cytokine balance, e.g. CCL2 promotes IL-4 production by T cells and inhibits IFN-γ production by Th1 cells (Hogaboam et al. 1998, 1999), and CCL5 downregulates IL-4, IL-5, IL-10, and IL-13 production by Th2 cells (Chensue et al. 1999).

It is a hallmark of the T-cell-mediated granulomatous inflammation that it is qualitatively different from an acute inflammatory reaction, particularly in terms of its dependence on adhesion co-receptors, for example, although the acute myelomonocytic infiltrate that occurs in response to infection with *Listeria monocytogenes* (an intracellular bacterium causing granulomatosis infantiseptica) can be experimentally abrogated by administration of monoclonal antibodies to CD11b (an integrin, part of the complement receptor 3 complex), T-cell-mediated granuloma formation is completely independent of this molecule (Mielke et al. 1989, 1997). Certain tissue selectivities also exist, e.g. recruitment of Th1 cells into the skin is dependent on E- and P-selectin ligands on T cells, whereas this probably does not hold true for homing into other organs (Smithson et al. 2001; Erdmann et al. 2002).

Some textbooks include, among DTH reactions, a form that is mediated by $CD8^+$ cytotoxic cells. These cells are induced during a primary immune response by MHCI presentation of proteasome-processed antigens derived from the cytosol. During the effector phase, these specific $CD8^+$ cells are capable of lysing infected cells, thereby causing tissue damage. As a result of this, and because these cells produce limited amounts of IFN-γ in response to antigen stimulation, they have also been defined as TC1 $CD8^+$ cells (Sad et al. 1995). Although these cells may contribute to the extent of DTH, the overwhelming evidence suggests that no skin DTH, and indeed no T-cell-dependent granuloma formation can occur without the active participation of $CD4^+$ cells, and that specific $CD8^+$ cells alone are incapable of initiating a granulomatous response (Mielke et al. 1988, 1992), at least in response to bacterial infections. TC1 cells clearly represent an important mechanism in combating viral infections and can be associated with significant T-cell-mediated tissue damage, but this takes the form of direct tissue cytotoxicity with subsequent extravasation of granulocytes to clear the debris, rather than the form of classic DTH described above with predominantly mononuclear cell infiltration and fibrin deposition.

Functions of granulomatous inflammation

Extracellular bacteria are ingested and killed by polymorphonuclear leukocytes, leading to abscess formation. Microorganisms that can survive intracellularly require a different strategy for their elimination or containment. The structure of a granuloma, with microbe-bearing macrophages at the center surrounded by T cells, affords a close cooperation of these specialized cells. T cells, by secreting macrophage-activating molecules such as IFN-γ or TNF, or via contact-dependent mechanisms such as granule exocytosis, reprogram the macrophage for bactericidal and bacteriostatic functions (Stenger and Modlin 1999; Ehrt et al. 2001). Conversely, macrophages and dendritic cells secreting cytokines and presenting antigens stimulate and select the type of T cell that ultimately decides the fate of the infectious lesion. Microorganisms may cause macrophage death by apoptosis or necrosis, and the removal of dead and dying cells and their replacement with freshly activated macrophages is a dynamic process guaranteed by the antigen-stimulated T cells in close proximity (Adams 1976).

In addition, the concept of physically walling off the offending organisms within a granuloma appears attractive, particularly when large parasites are involved. According to this view, granulomas would serve to contain microorganisms within a separate compartment, the perigranulomatous fibrotic reaction sealing off indigestible bacteria or parasites and preventing dissemination when macrophages burst or decay. In this secluded compartment, cytotoxic T cells may even lyse exhausted or ineffective macrophages in order to release bacteria that may subsequently be engulfed by newly recruited, activated macrophages, the granulomatous capsule preventing leakage into lymphatic or blood vessels (Kaufmann 1988; Saunders and Cooper 2000; Collins and Kaufmann 2001b). The granuloma is thus viewed as a local inflammatory reaction to prevent systemic sequelae of immune activation. Although this hypothesis has its merits, granulomas – like other tissues – are vascularized and may therefore not have the formidable barrier function ascribed to them. However, when a granuloma becomes entirely fibrotic or calcifies, complete sequestration of enclosed microorganisms is probably achieved.

DTH and pathology

Granulomatous inflammation, although necessary for containment of the infectious burden, displaces parenchymal tissue, thereby impairing organ function, such as pulmonary compliance and hepatic blood circulation. The extent of this damage depends on the size and exact location of the granulomas, and may remain undetected for long periods of time, e.g. when present in the mesenteric lymph nodes, yet cause rapid neurological defects when affecting the spinal cord.

One of the most severe forms of pathology associated with DTH is known as the Koch phenomenon, i.e. T-cell-mediated granuloma necrosis in response to mycobacterial antigens. When Robert Koch injected *M. tuberculosis*-infected guinea-pigs with a crude extract of *M.*

tuberculosis (old tuberculin) intradermally, he noted sloughing of the skin at the injection site as well as necrosis at original sites of *M. tuberculosis* implantation in the lung (Koch 1890). Tuberculin in non-sensitized guinea-pigs did not cause this pathology. Koch immediately proposed that this finding be put to clinical use in the diagnosis and therapy of tuberculosis (TB). The former is still in use today in the form of the diagnostic DTH reaction with appropriate doses of more purified protein extracts of *M. tuberculosis* cultures (see Figure 1, p. 706); the latter dismally failed when inappropriately high amounts were applied in severe cases of pulmonary TB, effectively killing patients because of the hyperinflammatory tissue necrosis that was induced. As pulmonary granuloma caseation and cavitation represent the detrimental outcome of a type 1 DTH reaction, we have termed this 'type 1 DTH-associated pathology' (Figure 3).

Another typical form of T-cell-mediated tissue damage caused by DTH is granuloma fibrosis. In chronic schistosomiasis, it is the vigorous granulomatous response, aggravated by fibrosis, rather than any toxicity of the parasite itself, that is responsible for the severe hepatic scarification and liver malfunction characteristic of this disease. As unrestrained granuloma fibrosis represents the detrimental outcome of a type 2 DTH reaction, we have termed this 'type 2 DTH-associated-pathology' (Figure 3). These two prototype pathological sequelae of a specific T-cell response are now described in more detail in terms of the cells and mediators involved. It should be noted, however, that these two types of pathology can overlap to a considerable extent, and that the complete dissociation as described below is merely an idealization for didactic purposes.

TYPE 1 DTH-ASSOCIATED PATHOLOGY: GRANULOMA NECROSIS DURING TUBERCULOSIS

Clinical manifestations of tuberculosis

Approximately one-third of the world population is infected with the causative agent of TB, *Mycobacterium tuberculosis*. Of infected individuals 90 percent will not develop any overt signs of disease throughout their lifetime, attesting to the potency of innate resistance and acquired immunity against TB. Five percent of those infected will come down with primary progressive TB within months of infection, and another 5 percent of those infected will develop post-primary, reactivating disease after a long period of 'latency', i.e. disease-free

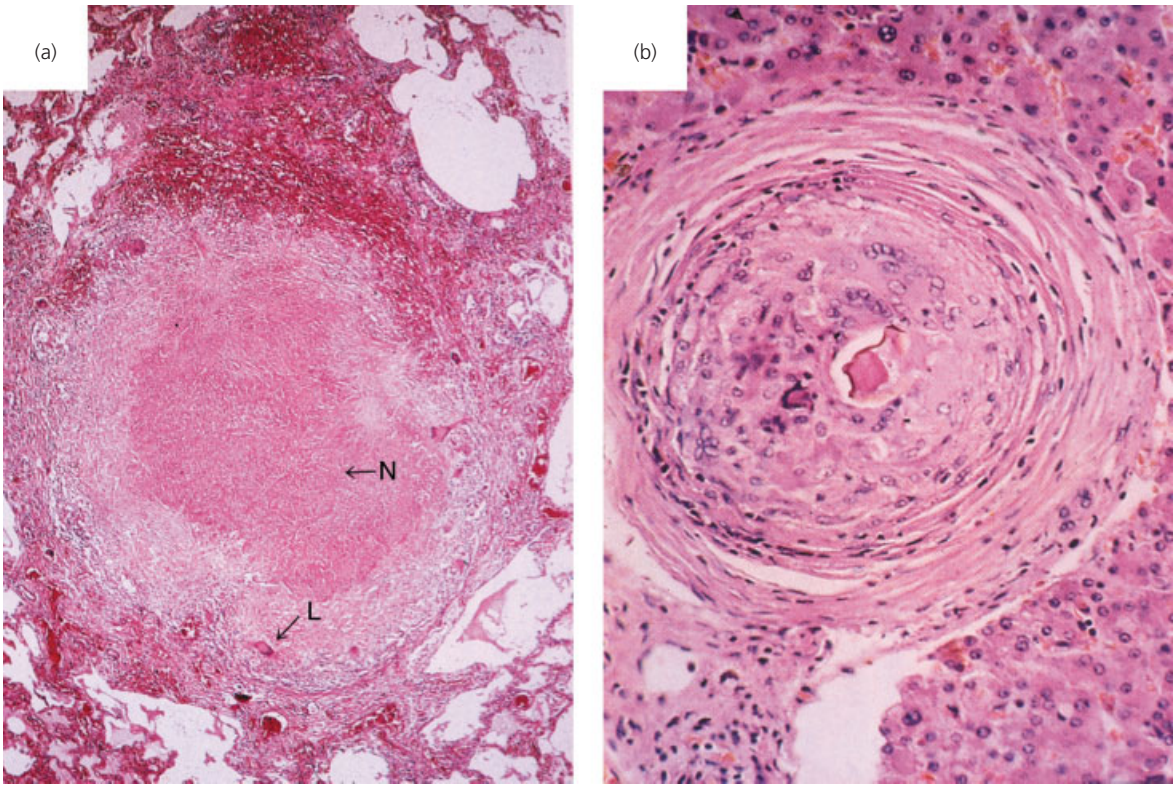

Figure 3 *Type 1 and type 2 DTH-associated pathology:* **(a)** *necrotizing granuloma in the lung of* Mycobacterium tuberculosis-*infected patient (type 1 pathology); N, necrosis; L, Langhans' giant cell;* **(b)** *fibrotic granuloma surrounding parasite egg in the liver of* Schistosoma mansoni-*infected patient (type 2 pathology). persistence of primary foci containing viable, nonreplicating mycobacteria. Each year, there are approximately 8 million new cases of TB world wide, and 1.8 million individuals will succumb to the disease, making TB the most deadly bacterial infection (World Health Organization 2002).

Tuberculosis is a systemic disease that becomes manifest most prominently in the lung. Prolonged episodes of fever, night sweats, chest or pleuritic pain, and pleural effusions are the most common initial symptoms of disease. Polymorphous pulmonary infiltrates appear soon after infection, are frequently restricted to one lung lobe, and are often associated with hilar lymphadenopathy. Progressive primary TB occurs when the initial inflammatory focus is unable to contain mycobacterial replication and the disease spreads to other parts of the lung, most often to the lower lung fields. Cough with variable amounts of sputum is the typical symptom, but dyspnea, chest discomfort, fever, chills, and weight loss also occur. Lung consolidation on chest radiographs is confluent and extensive, and single cavities may develop.

Post-primary disease develops when a lesion containing a previously 'dormant' organism reactivates. This organism may have been implanted years before during a primary infection that was successfully contained by the host's immune defenses. Reactivation is a consequence of a perturbed immune status of the host, i.e. old age, suboptimal nutrition, or therapy with immunosuppressive drugs. Disease onset is insidious and accompanied by cough and purulent sputum. Symptoms may range from weight loss, fatigue, and low-grade temperature to acute onset with fever, night sweats, and productive cough. Purulent-appearing sputum is produced whenever granuloma necrosis occurs. Some patients may present with hemoptysis, i.e. coughing of blood as a result of ulceration of granulation tissue or cavity vessels.

During primary infection, small numbers of *M. tuberculosis* invariably gain access to the circulation via the lymphatics and embolize to the capillary beds of most organ systems, e.g. liver, spleen, marrow, and brain. Almost always these metastatic foci heal by granulomatous encapsulation, sometimes with calcification, and with little tissue necrosis. Reactivation later in life may lead to localized extrapulmonary TB.

Miliary TB (so termed because of the gross appearance of the affected organ, 'covered with firm small white corpuscles, of the size of millet seeds' – Manget 1700) represents the unchecked hematogenous dissemination, either during primary infection or after reactivation of a latent focus of *M. tuberculosis*. This is most often seen in hosts with highly impaired cellular immunity.

Immunology and pathogenesis of disease

Mycobacterium tuberculosis is a slowly replicating acid-fast rod. Infection occurs after inhalation of droplet nuclei of 5 μm or less in diameter coughed up by an infected individual. These nuclei, containing 1–10 bacteria, are deposited in the alveoli where they are ingested by alveolar macrophages. Depending on the genetic resistance of an individual, either no further replication occurs or unchecked growth ensues until the incompetent macrophage is lysed, seeding bacteria to secondary sites and leading to local mediator release (TNF, IL-1, prostaglandins, vasoactive amines) and development of a small inflammatory focus. Digested fragments of mycobacteria are taken up by dendritic cells and transported to the local lymph node, where a specific immune response is initiated (Figure 4). TNF, IL-1, IL-6, IL-12, IL-18, and IL-27 are important soluble cofactors in the priming of naïve T cells, and costimulatory accessory molecules on the surface of antigen-presenting cells, such as CD80, direct the development of Th1 effector cells (Swain 2001; Colombo and Trinchieri 2002; Heath et al. 2002; Pflanz et al. 2002; Robinson and O'Garra 2002). Proliferation of T cells is dependent on IL-2, and further maintenance of long-lived memory cells requires IL-15 and IL-23, particularly in the case of $CD8^+$ cells (Umemura et al. 2001; Frucht 2002).

Circulating antigen-specific T cells home to sites of antigen deposition where $CD4^+$ cells cause granuloma formation. These 'tubercles' (literally: little hard nodes) are the hallmark of all mycobacterial infections (Figure 5). At this stage, depending on the bacterial load and the magnitude of the acquired immune response, either infection may be contained or growth and spreading of mycobacteria continue. In most cases, macrophages become sufficiently activated to kill mycobacteria, and tubercles undergo fibrosis and calcification, effectively sealing off the few remaining viable mycobacteria, usually for the lifetime of the host.

Protective immunity involves the secretion of IFN-γ by effector T cells which activates macrophages for bacteriostatic and bactericidal functions (Flynn and Ernst 2000; Shtrichman and Samuel 2001). These include the maturation and acidification of the phagolysosome, the deprivation of nutrients, as well as the generation of oxygen and nitrogen radicals, but the ultimate mechanisms of killing mycobacteria are poorly understood. This is particularly true for human macrophages in which even activation by TNF and IFN-γ results, at best, in bacteriostasis. Alternate mechanisms have therefore been invoked, such as T-cell-induced apoptosis of macrophages, the granule-mediated lysis of macrophages by T cells and killing of mycobacteria by granulysin contained in the granules, and the requirement for additional costimuli, such as CD40 ligand engagement or vitamin D_3 (Mazzaccaro et al. 1998; Stenger et al. 1999; Cho et al. 2000; Collins and Kaufmann 2001b; Hogan et al. 2001). On the other hand, TGF-β (produced in significant quantities within tuberculous lesions) undermines host immune responses, because it promotes T-cell suppression, macrophage deactivation, and tissue

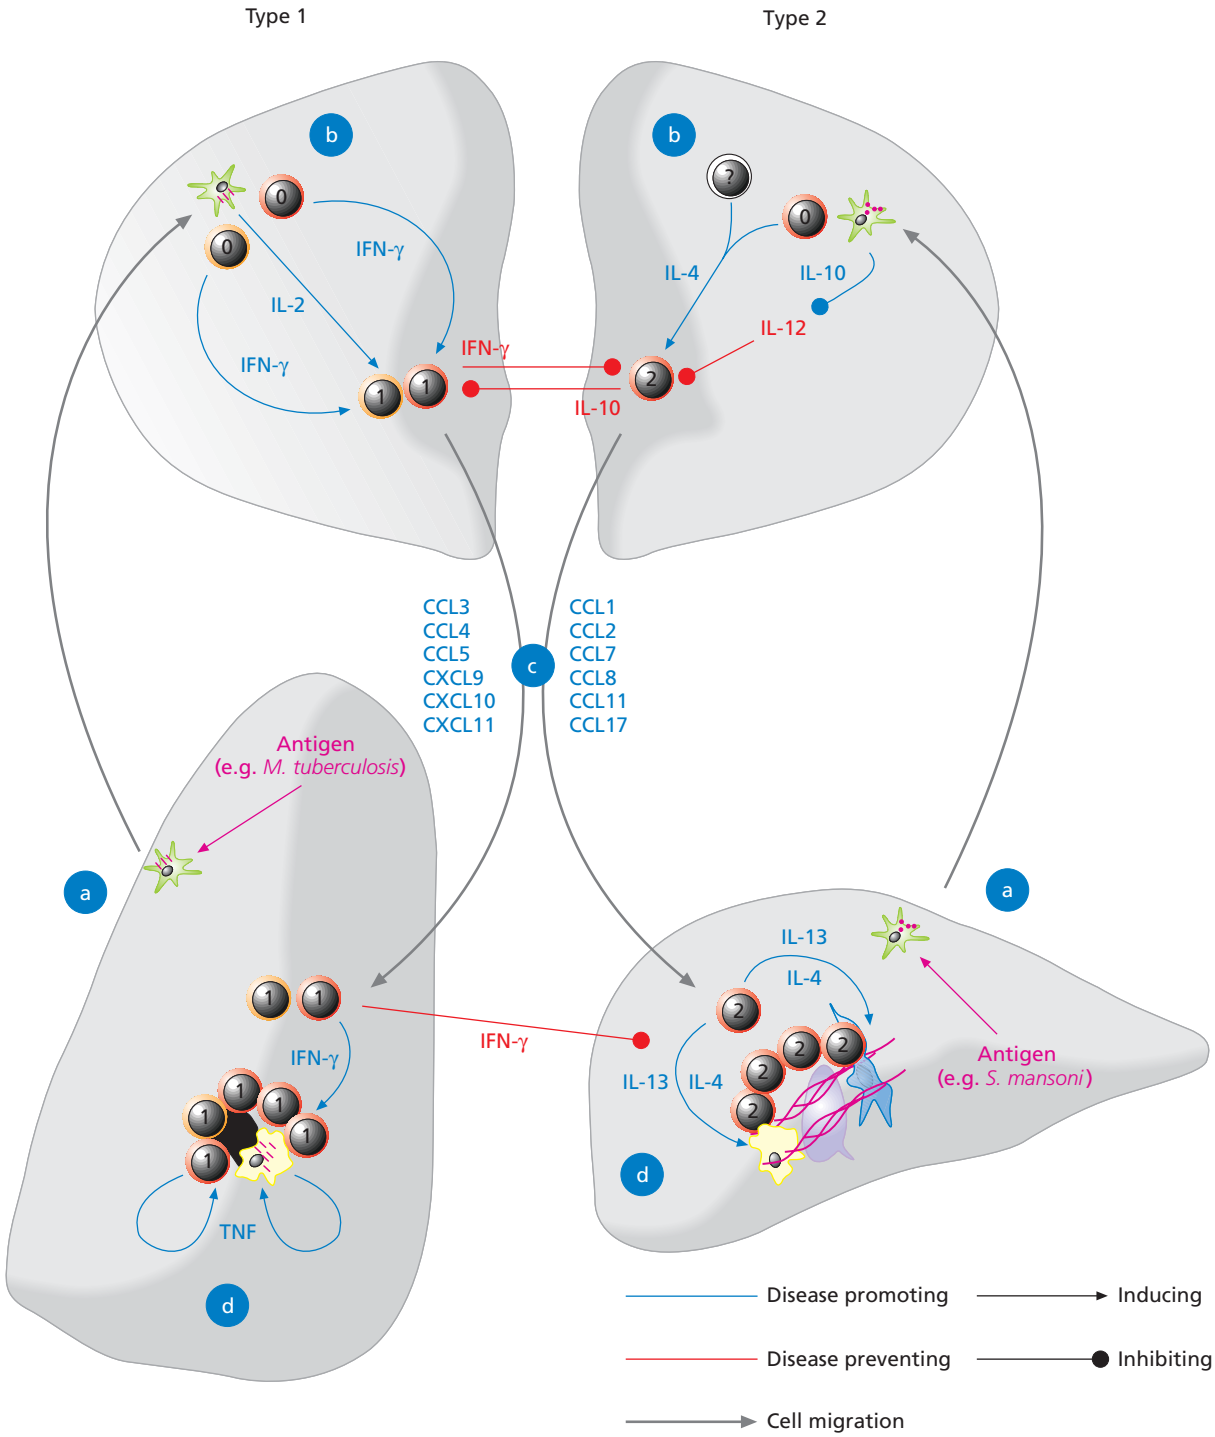

Figure 4 *Mechanisms of granuloma formation:* **(a)** *antigen uptake and activation of dendritic cells in infected tissue, e.g. lung or liver;* **(b)** *priming of specific T cells in draining lymph node;* **(c)** *cell recruitment of specific T cells into infected tissue by chemokines; and* **(d)** *granuloma formation and effector response of T cells in infected tissue. 0=Th0, 1=Th1, 2=Th2. For details, see text.*

destruction (Toossi and Ellner 1998). In the absence of significant immunity, i.e. in infants and immunodeficient adults, there is progressive spread with tuberculous pneumonia or miliary TB.

In the face of developing immunity and high antigenic load, there is frequently necrosis of macrophages at the center of the granulomas. Within these necrotic areas, mycobacteria are located extracellularly and do not replicate well. When the necrotic center of a granuloma liquefies, a cavity is formed and multiplication of *M. tuberculosis* resumes. When bronchial erosion occurs, the infective material may disseminate through the

airways to other sites in the lung or may be coughed up, creating infectious aerosols.

In those cases in which T-cell immunity is grossly impaired (e.g. in patients with AIDS), rapid growth of mycobacteria results in widespread tissue necrosis without granulomatous encapsulation. This form of nondemarcated tissue necrosis is probably a consequence of the inherent cytotoxic nature of *M. tuberculosis* and must be clearly differentiated from the typical form of granuloma caseation brought about by specific T cells.

Morphology of type 1 DTH-associated pathology

A typical tuberculous lesion is composed of coalescent granulomas, containing epithelioid cells surrounded by a zone of fibroblasts and lymphocytes. In mice, most of the T lymphocytes are of the $CD4^+$ subtype, but in the periphery $CD8^+$ cells also exist (Gonzalez-Juarrero et al. 2001). There is a considerable number of B cells, often arranged as lymphoid follicles, present in mature granulomas. A study using in situ hybridization and immunohistology to analyze cytokines present in human tuberculous lesions showed that granulomas usually stain positive for IL-12p40, IFN-γ, and TNF transcripts and protein, with a minority also showing IL-4 expression (Fenhalls et al. 2000, 2002). IL-4 positive granulomas were always concomitantly positive for IFN-γ, and necrotic granulomas were always positive for TNF.

As a result of macrophage necrosis within the granuloma, caseation is usually present in the centers of these tubercles – so called because of the cheesy appearance when cut by a pathologist's knife (Figure 6). Adjacent to the caseous center, a large number of neutrophils are often found. In addition to 'necrosis' as judged by light microscopic evaluation, there is significant apoptosis of both T cells and macrophages in mature granulomas (Fayyazi et al. 2000).

As the lesions progress, more tubercles coalesce to create a confluent area of consolidation. At this stage, the entire area may be converted to a fibrocalcific scar, or the residual caseous debris may become walled off by collagenous connective tissue. However, when the tubercle erodes into a bronchus, drainage transforms it into a cavity (Figure 6). Cavitary fibrocaseous TB may affect one, many, or all lobes of both lungs in the form of isolated small tubercles, confluent caseous foci, or large areas of caseation necrosis (Kobzik and Schoen 1994).

Delayed-type hypersensitivity-associated pathology in the form of granuloma necrosis is therefore not only potentially hazardous to the diseased individual, aggravating tissue damage and organ malfunction, but also epidemiologically relevant, because necrosis, liquefaction, and bronchial erosion ultimately favor the spread of viable mycobacteria into the environment in an aerosolized form.

Mechanisms of granuloma necrosis

In order to dissect a process as complex as T-cell-mediated tissue injury, it is imperative to have a reproducible animal model that mimics the pathology occurring in

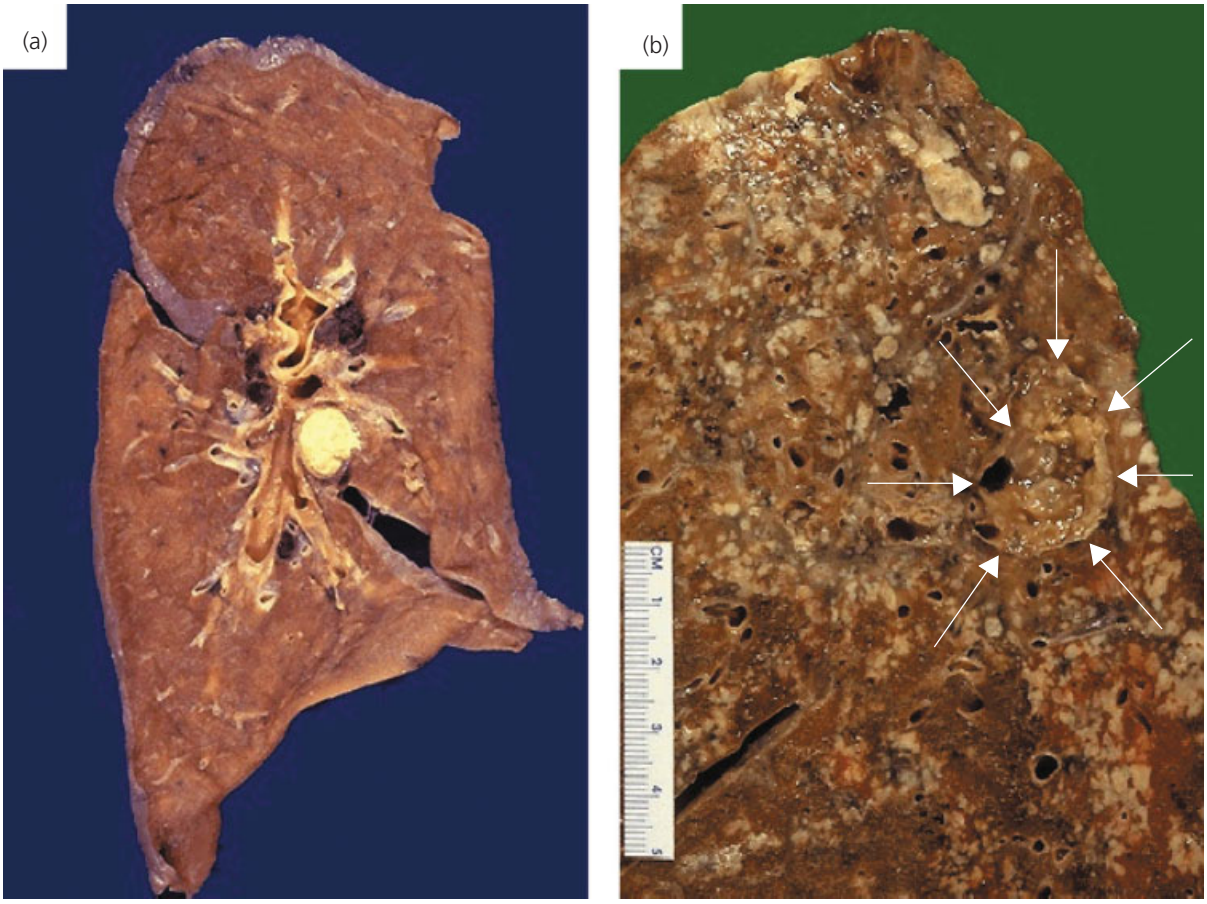

Figure 6 *Type 1 pathology: caseous necrosis and cavity formation in the lungs of tuberculosis patients.* **(a)** *Caseating granulomatous lesion in a hilar lymph node.* **(b)** *Extensive caseous necrosis throughout the lung with prominent cavitation (area demarcated by arrows). humans and allows for a mechanistic study of the factors involved (McMurray et al. 1996).

Aerogenic infections in rabbits faithfully reproduce the pathology present in humans, including liquefaction of caseous necrosis and subsequent cavity formation (Figure 7). However, most studies have remained purely descriptive of this phenomenon because immunological reagents are missing to dissect, at the molecular level, the processes underlying granuloma necrosis. A few studies demonstrated that activated macrophages surrounding the caseous center stain positive for β-galactosidase, acid phosphatase, and cathepsin D which may implicate lysosomal enzymes such as proteases, lipases, or nucleases in the liquefaction process (Dannenberg 1968; Dannenberg and Sugimoto 1976; Suga et al. 1980; Converse et al. 1996). Moreover, the endothelial adhesion molecules ICAM-1 and VCAM were found to be preferentially expressed during the chronic stage of infection suggesting their involvement in the granulomatous, rather than acute inflammatory, response (Abe et al. 1996). Aerogenic infections in guinea-pigs also induce caseous necrosis in developing pulmonary granulomas. This is associated with a marked DTH skin response. Again, mechanistic studies on the molecular mediators of tissue necrosis have been lacking because of a paucity of immunological reagents to measure them.

Aerogenic infection in laboratory mice with *M. tuberculosis* is not followed by granuloma necrosis, but is rather associated with chronic interstitial fibrosis (North 1995; Rhoades et al. 1997). However, when mice deficient in the γδ T-cell-receptor (TCR)-positive cell subset are infected, they develop a purulent form of granuloma with many neutrophils infiltrating necrotic areas at the center of the granuloma (D'Souza et al. 1997). Infection with *Listeria monocytogenes* also results in centrally necrotic and purulent granulomas (Mombaerts et al. 1993). These data suggest that γδ T cells perhaps play an important role by influencing local cellular traffic, promoting the influx of lymphocytes and monocytes, and limiting the access of inflammatory cells that do not contribute to protection but may cause tissue damage. Alternately, γδ T cells may produce cytokines and/or chemokines that regulate the potentially harmful effect

of a hyperinflammatory Th1 reaction initiated by αβ-TCR$^+$ CD4$^+$ T cells.

Fortuitously, aerogenic infection in mice with a highly virulent strain of *M. avium* (the causative organism of avian TB) results in progressive granuloma caseation with perigranulomatous fibrosis, strongly resembling the pathology occurring in human TB patients (Benini et al. 1999). This model is therefore perfectly suited for the molecular analysis of granuloma necrosis, because immunological tools, such as knock-out mice, may be applied. Using this model, αβ-TCR$^+$ T cells of the CD4$^+$ subset are found to be necessary for granuloma necrosis, whereas γδ-TCR$^+$ cells and CD8$^+$ cells do not contribute (Figure 8) (Ehlers et al. 2001). Perforin and apoptotic mechanisms are not required for necrosis in this model (Florido et al. 2002). However, IL-12 and IFN-γ are essential for granuloma necrosis, and in the absence of IL-10 granuloma necrosis is slightly accelerated (Ehlers et al. 2001; Florido et al. 2002). Most interestingly, the absence of NOS-2 does not impact on granuloma necrosis, revealing that IFN-γ-induced mechanisms mostly associated with antibacterial protection (such as induction of NOS-2) need not necessarily coincide with mechanisms that lead to tissue destruction (Ehlers et al. 2001). It was hypothesized that IFN-γ may preferentially induce a variety of chemokines with anti-angiogenic effects, and that reduced vascularization may then lead to granuloma hypoxia and subsequent necrosis, similar to a scenario previously demonstrated in infection-associated tumor regression (Hunter et al. 2001).

Tumor necrosis factor has long been postulated to be directly involved in caseation necrosis, because infection of cells with *M. tuberculosis* rendered them highly sensitive to killing by TNF in vitro (Filley et al. 1992). Moreover, DTH sites were particularly necrosis prone after TNF injection, when small amounts of IL-4 were also present (Hernandez-Pando and Rook 1994; Rook and Zumla 2001). Finally, treatment of *M. tuberculosis*-infected mice with recombinant TNF resulted in increased inflammation in the lungs and accelerated mortality (Moreira et al. 2002).

Studies in *M. tuberculosis*-infected TNF- and TNFRp55-deficient mice are more difficult to interpret, because TNF is necessary for granuloma initiation and maintenance as well as antibacterial protection. TNF-deficient mice will therefore succumb to excessive bacterial loads in a completely necrotic lung, a scenario more reflective of primary progressive TB in immuno-

deficient individuals (Flynn et al. 1995). Further studies using different microbial challenges, such as *M. avium* and *Corynebacterium parvum*, established that the absence of TNF signaling is associated with an excessive inflammatory response, and (as in the aerosol model of necrosis) is dependent on T cells and IL-12, probably reflecting dysregulated inflammation (Marino et al. 1997; Benini et al. 1999; Ehlers et al. 2000). TNF (and also IFN-γ), possibly via the induction of NOS-2, therefore also serve to downregulate an exacerbated inflammatory response, in part by inducing apoptosis of effector T cells (Kanaly et al. 1999; Chu et al. 2000; Dalton et al. 2000; Cooper et al. 2002).

The frequent presence of granulocytes close to the necrotic center of granulomas is intriguing. It is possible that they act merely as scavengers clearing the debris, but they may also be the source of cytokines and chemokines (such as CXCL9 and CXCL10), amplifying the tissue-damaging loop by recruiting more T cells (Gasperini et al. 1999). Granulocytes may also degranulate, contributing to tissue destruction by a similar mechanism to that postulated for activated macrophages, i.e. the release of aggressive lysosomal proteases and other hydrolyzing enzymes (Dannenberg and Sugimoto 1976).

TGF-β has been implicated in the pathogenesis of many diseases that are associated with tissue destruction and fibrosis (Border and Noble 1994). It promotes the production and deposition of a collagen matrix, but it also increases the production of macrophage collagenases (Wahl et al. 1993). As it is a strong chemotactic molecule for monocytes and polymorphonuclear cells, both of which are rich sources of metalloproteases, TGF-β may be particularly involved in tissue remodeling, with a potential bias towards tissue destruction and scarring (Wahl et al. 1987; Toossi and Ellner 1998).

Finally, degradation of collagen and other matrix proteins is achieved by a family of metalloproteases, which are dependent on zinc ions for their activity (Parks and Shapiro 2001; Brinckerhoff and Matrisian 2002). Metalloproteases comprise: (1) interstitial collagenases, which cleave the fibrillar collagen types I, II, and III; (2) gelatinases, which degrade amorphous collagen as well as fibronectin; (3) stromelysins, which act on a variety of matrix components, including proteoglycans, laminin, fibronectin, and amorphous collagens; and (4) matrilysin, which plays a role in innate immunity of epithelial barriers. These enzymes are produced by several cell types (fibroblasts, macrophages, neutrophils, epithelial cells), and their secretion is induced by many stimuli, including growth factors platelet-derived growth factor (PDGF), fibroblast growth factor (FGF)), cytokines (IL-1, TNF, TGF-β), and phagocytosis. They are elaborated in a latent form that can be activated by oxygen radicals and proteases produced during inflammation, and can be inhibited by specific tissue inhibitors of metalloproteases (TIMP). Degrading collagen is essential in wound repair, and metalloproteases may therefore not only promote, but also alleviate tissue destruction in DTH-associated pathology, depending on the stage of disease (Parks and Shapiro 2001; Winkler and Fowlkes 2002). Macrophage metalloelastase, by cleaving elastin, generates fragments that are chemotactic for monocytes, and may perpetuate macrophage accumulation, leading to progressive and chronic lung destruction (Senior et al. 1980). Table 2 summarizes some of the mediators and mechanisms that contribute to granuloma necrosis.

Strategies to reduce granuloma necrosis: Implications for vaccine development

The importance of defining the molecular pathways ultimately causing type 1 DTH-associated pathology is highlighted by the results of recent immunization studies in guinea-pigs. Animals that received a DNA vaccine encoding heat shock protein 60 of *M. tuberculosis* – published as highly efficacious as a therapeutic vaccine (Lowrie et al. 1999) – succumbed to infection significantly earlier than controls showing widespread caseation necrosis in their lungs (Turner et al. 2000). Thus, more immunogenic vaccines simply triggering more of the mediators common to antibacterial protection and granuloma necrosis will inevitably result in more tissue damage, effectively rendering them useless. The trick will be to inhibit, or modulate the pathways involved in DTH-associated pathology while, at the same time, boosting the mechanisms involved in antibacterial protection.

Some investigators have suggested that this may be possible with a careful selection of the antigens in vaccine preparations, i.e. the use of antigens common to all mycobacterial species and avoidance of the species-specific *M. tuberculosis* antigens (Rook and Hernandez-Pando 1996; Rook et al. 2001). Thus far, vaccine and immunotherapy trials have not produced convincing proof of this hypothesis (Durban Immunotherapy Trial Group 1999).

A different strategy is specifically to target $CD8^+$ cells in a vaccine protocol, reducing $CD4^+$ T cell-mediated DTH while possibly exploiting granule-mediated pathways of antibacterial protection (Kaufmann 2000; Stenger and Modlin 1998; Stenger et al. 1998; Collins and Kaufmann 2001a). Given the uncertainty concerning the true level of protection $CD8^+$ T cells afford in vivo against *M. tuberculosis* challenge, this approach may be only part of the solution (Sousa et al. 2000; Mogues et al. 2001). If it turns out that the distinction between antibacterial protection and tissue damage (in terms of mediators required) is more of a quantitative rather than of a qualitative nature, 'differential vaccination' may be altogether out of reach.

TYPE 2 DTH-ASSOCIATED PATHOLOGY: GRANULOMA FIBROSIS IN SCHISTOSOMIASIS

Manifestations of clinical schistosomiasis

Schistosomiasis is a disease of the tropical world. According to the World Health Organization, the disease is endemic in 74 countries, affecting about 200 million people (Pearce and MacDonald 2002). The causative agents are digenic trematode worms, also called blood flukes. Three species are important causes of human infection: *Schistosoma mansoni*, *S. japonicum*, and *S. haematobium*. The adult forms of *S. mansoni* and *S. japonicum* live in the portal and mesenteric veins; *S. haematobium* inhabits the vesical plexus of the bladder. Humans are the principal definitive host during the life cycle of these three species of schistosomes and adult worms live in the venous systems of the intestine. The female worm inhabits a groove in the lateral edge of the male's body and produces from 300 (*S. mansoni*) to 3000 (*S. japonicum*) eggs every day. These eggs pass through the venule walls, cross the intestinal mucosa, find their way into the lumen of the bowel, and are excreted with the feces (Figure 9). In fresh water, the eggs hatch and release motile ciliated miracidia which penetrate the body of the intermediate host, usually a snail of the genus *Biomphalaria* (*S. mansoni*) or *Oncomelania* (*S. japonicum*). The miracidia multiply asexually inside the snail; within a few weeks, hundreds of motile fork-tailed cercariae emerge. When the cercariae encounter human skin they penetrate it, lose their tails, and change into schistosomula forms, which migrate to the lungs and liver. In approximately 6 weeks they mature into adult worms and pass through the venous system to their final habitat. The life span of the worm is 5–10 years, and by a variety of mechanisms it is capable of evading the host immune response. The worms feed on host erythrocytes and body solutes, and their presence is innocuous to the host. Some of the eggs deposited by the females into the bloodstream are excreted with the feces. However, eggs that do not reach the intestinal lumen are swept into the portal circulation and are trapped in the intestinal wall, the liver, or the lung. This continuous egg deposition induces a chronic granulomatous response in the host that is responsible for the major disease syndrome of chronic schistosomiasis.

The two main clinical conditions, acute and chronic schistosomiasis, are associated with different immune responses. Acute schistosomiasis in humans is a debilitating febrile illness that can occur before the appearance of schistosoma eggs in the feces and which peaks

generally between 6 and 8 weeks after infection (Rabello 1995). In chronic schistosomiasis, there is a progressive increase in egg burden which affects primarily the intestines and liver. Antigenic properties of the parasite induce a strong immune response resulting in granuloma formation and fibrosis around the eggs in these organs (Figure 9). This may result in portal hypertension, massive splenomegaly, and gastrointestinal bleeding from esophageal varices. Patients experience fatigue, abdominal pain, and diarrhea, and in the most severe cases jaundice and liver failure. Occasionally eggs may bypass the liver via the portosystemic collateral circulation and give rise to granulomas in the lung, with pulmonary hypertension and cor pulmonale, or lesions in the brain or spinal cord, which may present as space-occupying lesions, generalized encephalopathy, or transverse myelitis. The severity of the disease directly correlates with the number of eggs present in the tissues. The liver sustains the most severe damage in chronic schistosomiasis, because the chronic granulomatous inflammation results in severe fibrosis which accumulates over the long period of the disease.

Immunology and pathogenesis of schistosomiasis

Schistosomiasis causes a range of illnesses, the development of which is influenced to a large extent by the nature of the induced immune response and its effects on granuloma formation and associated pathologies in target organs (Boros 1999; Dunne and Pearce 1999; Cheever et al. 2000). Host genetics, parasite burden, and sensitization to schistosoma antigens all influence the development of the immune response and, thus, disease severity.

In contrast to early studies showing the participation of eosinophils and IgE in in vitro killing of *S. mansoni* larvae in antibody-dependent cellular cytotoxicity (ADCC) reactions (Romagnani 1996), in vivo studies employing mouse models argue against a function of IgE and eosinophils and support a role for Th1 responses in protection against *S. mansoni* (de Andres et al. 1997; King et al. 1997). During the larval migration and maturation period, resistance is dependent on $CD4^+$ T cells and is associated with a Th1 cytokine response (Vignali et al. 1989; Sher et al. 1990). In particular, IL-12-induced IFN-γ is mandatory for resistance after immunization with irradiated parasites (Smythies et al. 1992; Wilson et al. 1996; Anderson et al. 1998). IFN-γ-activated macrophages and endothelial cells kill larval schistosomes in vitro via an arginine-dependent mechanism involving NO production (James and Glaven 1989; Oswald et al. 1994). In vivo, most parasites are eliminated as they traverse the lungs of immunized mice (Dean and Mangold 1992; Wilson et al. 1996) and NOS-2 can be identified in the pulmonary inflammatory foci around the migrating larvae (Wynn et al. 1994). Moreover, larvacidal properties of NO represent an important effector mechanism because NOS-2-deficient mice display a reduced resistance to *S. mansoni* challenge (James et al. 1998).

Some Th2 effector mechanisms, however, also contribute to protection against *S. mansoni*. In particular, IL-4Rα-mediated signaling by IL-4 and IL-13 participates in the development of immunity. In immunization studies, the defective Th2-type antibody response (i.e. no IgG1 or IgE) in IL-4Rα-deficient mice was associated with increased parasite loads which could be partially prevented by serum transfer (Mountford et al. 2001). As IgE has no protective role against challenge with *S. mansoni* (King et al. 1997; de Andres et al. 1997), protection is probably associated with the IgG1 antibody subclass.

In chronic schistosomiasis, the pathology is predominantly caused by the host reaction to parasite eggs, which are laid in the portal venous system and subsequently trapped in the liver and intestine (Cheever

1972). Although Th2 responses have a beneficial role in modulating potentially life-threatening disease during the initial stages of schistosomiasis, prolonged Th2 responses are responsible for the development of egg-induced hepatic fibrosis and chronic morbidity (Cheever et al. 2000). Even though IL-4 is the primary cytokine driving the differentiation of $CD4^+$ T cells into the Th2 subset, fibrotic pathology in schistosomiasis is not ameliorated in IL-4-deficient mice (Wynn et al. 1993; Cheever et al. 1994; Metwali et al. 1996; Pearce et al. 1996; Chensue et al. 1997b). However, granuloma formation and fibrosis do depend on IL-4Rα-mediated signaling (Kaplan et al. 1996, 1998). As IL-4 and IL-13 share the IL-4Rα as a common receptor component and both activate the Stat6 signaling pathway (Brombacher 2000; Hölscher 2003), pathology in chronic schistosomiasis is a result of IL-13-mediated mechanisms. *Schistosoma*-infected mice in which IL-13 is either neutralized by treatment with soluble IL-13Rα_2-Fc (Chiaramonte et al. 1999a) or absent (IL-13-deficient mice) (Fallon et al. 2000) fail to develop the severe hepatic fibrosis – marked by extensive collagen deposition – that normally occurs during infection, and survive longer (Figure 10). Th2 responses are maintained in IL-13-deficient animals, and blocking IL-13 in IL-4-deficient mice does not perturb the Th1/Th2 cytokine balance (Chiaramonte et al. 1999a; Fallon et al. 2000). However, fibrosis is maximally reduced in these mice, again emphasizing the important role played by IL-13 in fibrogenesis.

Given its critical role in fibrosis, differences in the expression of IL-13 could provide a simple explanation for the different degrees of fibrosis that different inbred mouse strains develop after infection with *S. mansoni* (Cheever et al. 1987). However, there is no correlation between the expression of IL-13 and the severity of fibrosis in these strains (Chiaramonte et al. 2001). On the other hand, IFN-γ and IL-10 are key regulatory cytokines in fibrosis (Czaja et al. 1989; Hoffmann et al. 2000; Louis et al. 2000; Nelson et al. 2000; Chiaramonte et al. 2001). In schistosomiasis, the antifibrotic effects of the Th1 cytokine IFN-γ are well documented (Czaja et al. 1989; Wynn et al. 1995). IFN-γ directly downregulates the synthesis of extracellular matrix components (Stephenson et al. 1985), and the IL-13:IFN-γ ratio is predictive of the magnitude of fibrosis (Chiaramonte et al. 2001). In humans, severe hepatic fibrosis correlates with a mutation in the IFN-γR1 (Dessein et al. 1999), and can be explained by the lack of effective suppression of fibrogenesis by IFN-γ. High IL-13 and low IL-10 levels are also predictive of severe fibrosis in inbred mice, whereas inbred mice displaying a low IL-13:IL-10 ratio tend to develop a more modest degree of fibrosis after infection with *S. mansoni* (Chiaramonte et al. 2001). In summary, the magnitude of fibrosis is controlled by the profibrogenic activities of IL-13 and antifibrotic effects of IFN-γ and IL-10.

Morphology of type 2 pathology

Histological examination of lesions from chronically infected individuals with type 2 pathology shows granulomas to be composed mainly of lymphocytes, macrophages, and eosinophils, exhibiting a wide range of granuloma size around deposited eggs from *S. mansoni* (Boros 1989). The cellular constituents of murine liver granulomas also comprise lymphocytes, plasma cells, macrophages, epithelioid and giant cells, eosinophils, neutrophils, mast cells, and fibroblasts (Stenger et al. 1967; Smith 1977). In particular eosinophils and mast cells produce several Th2-associated cytokines (Sabin et al. 1996; Woerly et al. 1999) and are often described as important effector cells in a variety of Th2-mediated pathological disorders. However, there is no correlation between the magnitude of hepatic fibrosis and the cellular composition of the lesions (Chiaramonte et al. 2001).

In general, the development of fibrous tissue is part of the normal process of healing after injury. Nevertheless, in schistosomiasis, fibrosis enhances the disease pathology and greatly contributes to the mortality after infection with *S. mansoni* (Friedman et al. 2000). Fibrotic changes are ranked on the basis of ultrasound patterns that provide a quantitative tool for assessing the severity of disease (Hatz 2001). After infection with *S. mansoni*, the fibrotic reaction is characterized by collagen deposition and collagen synthesis in fibrotic livers increases up to 40-fold over that of normal livers (Dunn and Kamel 1981). Consequently, type I, type III, and B collagens are found in portal spaces, fibrous septa, and granulomas (Biempica et al. 1983). Hepatic fibrosis is mostly associated with circumoval granulomas (see Figure 3b, p. 710, and 35.9) and follows the granulomatous inflammatory response occurring at the site of egg deposition (Dunn et al. 1977; Dunn and Kamel 1981). Total liver collagen production positively correlates with egg load (Cheever et al. 1983), but there is no direct relationship between granuloma size and the degree of fibrosis (Hood and Boros 1980).

In *S. mansoni* infection, cells within hepatic granulomas are potentially harmful to adjacent parenchymal cells, because they are in a metabolically activated state, capable of secreting a number of tissue-destroying substances. During phagocytosis, cell activation, or cell death, these mediators diffuse from the granulomas and damage tissue parenchymal cells. Potential tissue-damaging agents that are released in granulomas are lysozyme, β-glucuronidase, collagenase, elastase, proteases, prostaglandins, leukotrienes, superoxide anions, IL-1, and type 1 interferons (James and Glaven 1989). Indeed, healed granulomas usually leave behind scar tissue in their vicinity, indicating focal damage and repair (Von Lichtenberg 1975).

Mechanisms of granuloma fibrosis in schistosomiasis

The effects of IL-13 on fibrosis are direct and are not dependent on induction of other profibrotic mediators (Lee et al. 2001) or perturbations in the Th1/Th2 cytokine response (Wynn et al. 1995). IL-13 receptors are expressed on fibroblasts (Murata et al. 1998) and IL-13 increases adhesion molecule and inflammatory cytokine expression (Doucet et al. 1998). Moreover, fibroblasts of different origin are able to respond to IL-13 with collagen production (Chiaramonte et al. 1999a; Oriente et al. 2000). Although IL-13 and IL-4 are both capable of promoting collagen production in fibroblasts (Oriente et al. 2000) after infection with *S. mansoni*, expression of IL-13 largely exceeds that of IL-4 (Chiaramonte et al. 1999a). In the pulmonary granuloma model IL-4 is more transiently expressed after egg exposure, whereas expression of IL-13 is much more sustained over time and is observed at greater levels than IL-4 in the granulomatous tissues (Chiaramonte et al. 1999b).

Hepatic fibrosis can be reduced when the *S. mansoni* egg-specific response is directed into a Th1- rather than a Th2-dominated reaction. This is accomplished by sensitization to schistosome egg antigens in the presence of IL-12 or CpG oligonucleotides (Wynn et al. 1995). Several Th1-associated mediators are believed to be involved in preventing the fibrotic response (Hoffmann et al. 1998), particularly NOS-2 (Hesse et al. 2000). NOS-2-deficient mice that have been sensitized with schistosome egg antigen and IL-12 develop a Th1-dominated response, but fail to control the granulomatous inflammation and display a marked exacerbation of hepatic fibrosis. Therefore, the critical downstream component that controls fibrosis in a Th1-dominated response is the functional activity of NOS-2-expressing cells.

As NOS-2 shares L-arginine as a substrate with arginase, substrate depletion by either enzyme is a key regulatory mechanism (Rutschman et al. 2001) and the differential expression of NOS-2 and the hepatic isoform of arginase (Arg-1) is important for regulating or promoting fibrosis. Macrophages are a prominent participant in *S. mansoni* egg-induced granuloma and are the primary producers of NOS-2 and Arg-1. Although it is not yet known which cells, besides macrophages, express Arg-1 after infection with *S. mansoni*, granuloma formation correlates with high arginase activity (Hesse et al. 2001). The Th1 cytokines IFN-γ and TNF activate NOS-2 production in 'classically activated' macrophages, thus regulating hepatic fibrosis by substrate depletion for Arg-1. On the other hand, the profibrotic Th2 cytokine IL-13 induces Arg-1 activity in 'alternately activated' macrophages (Modolell et al. 1995), and Th2-driven arginase expression and activity are the critical component in the development of type 2 pathology (Hesse et al. 2001) (Figure 11).

Arg-1 is an essential enzyme of the urea cycle and is expressed at high levels in hepatocytes. The enzyme hydrolyses L-arginine to urea and L-ornithine; therefore, its main function in the liver is the detoxification of ammonia. As L-ornithine, a product of arginase activity, is a necessary metabolite for the production of prolines which in turn control collagen production, arginase activity is linked to hepatic fibrosis after *S. mansoni* infection. The direct involvement of the arginase biosynthetic pathway in type 2 pathology was tested by blocking the L-ornithine-dependent synthesis of polyamines. After blocking ornithine carbamoyltransferase (ODC), competition between ODC and ornithine aminotransferase (OAT) for L-ornithine is eliminated and hepatic fibrosis after infection with *S. mansoni* increases (Hesse et al. 2001). Thus, the utilization of L-ornithine by OAT, which increases the synthesis of prolines (the basic building block of collagen), could explain the enhanced collagen deposition. An earlier study of schistosomiasis had already shown that fibrosis is directly controlled by the availability of proline (Dunn et al. 1981). As IL-4/IL-13-activated macrophages are an important source of proline (Hesse et al. 2001), macrophages act as important controllers of type 2 pathology. However, recently established macrophage-specific IL-4R-α-deficient mice (Herbert et al. 2004), carrying a defective receptor for IL-4 and IL-13 only on macrophages revealed that other cell types such as fibroblast are involved in the development of type 2 pathology.

Biochemically, collagen synthesis occurs by conversion of proline into hydroxyproline. The endogenous proline used for collagen synthesis diffuses into hepatic granulomas and is hydroxylated by prolylhydroxylase, an enzyme that is greatly elevated within granulomatous livers (Dunn et al. 1979). At the peak of granuloma formation, vigorous collagen production is coincident with maximal lesion size after which synthesis declines. However, at this time the collagen content remains maximal because enzymatic degradation of the connective tissue matrix is inhibited and collagen accumulates in hepatic lesions (Dunn et al. 1979). Intragranulomatous protease inhibitors were identified as α_2-macroglobulin and α_1-antiprotease (Truden and Boros 1988). The net effect of synthesis versus degradation results in remodeling of the affected tissues.

Fibroblasts, macrophages, and smooth-muscle cells have all been identified as initiators of hepatic granuloma fibrosis (Boros 1989; Hesse et al. 2001). Granuloma fibroblasts produce CCL2 and CCL3 and are implicated in promoting leukocyte recruitment, granuloma growth, and maintenance of the granulomatous lesion (Lukacs et al. 1994a). Migration of fibroblasts to the site of injury and their subsequent proliferation are triggered by growth factors, such as PDGF, epidermal growth factor (EGF), FGF, and TGF-β, and fibrogenic cytokines derived in part from inflammatory macrophages (Mornex et al. 1994). Some of these growth factors also stimulate synth-

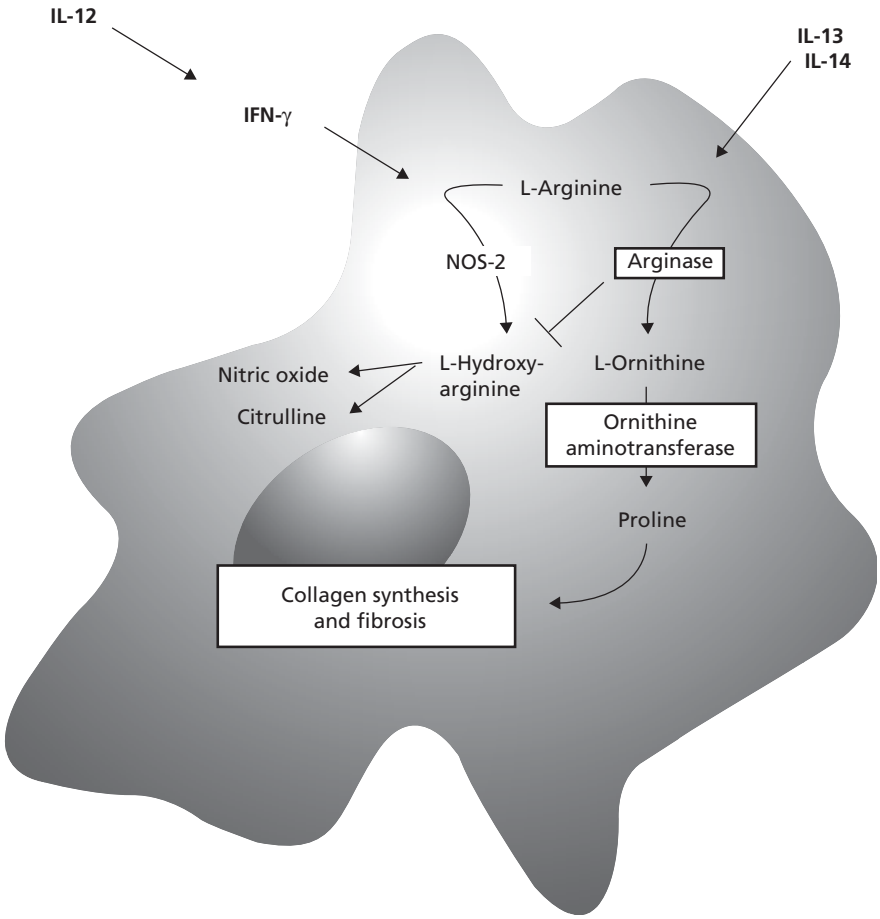

Figure 11 *Mechanisms of granuloma fibrosis in type 2 pathology. For details, see the text.*

esis of collagen and other connective tissue molecules and modulate the synthesis and activation of metalloproteases, enzymes that serve to degrade these extracellular matrix components (Winkler and Fowlkes 2002). Mice overexpressing TGF-β in the liver develop multiple tissue lesions including hepatic fibrosis and hepatocyte apoptosis (Sanderson et al. 1995). The inhibition of TGF-β action by the administration of agents that bind TGF-β or block TGF-β expression is effective in experimental models, but its efficacy and safety in human liver fibrosis remain unknown (Gressner et al. 2002).

Strategies to prevent granuloma fibrosis: implications for immunotherapy

Findings from experimental schistosomiasis clearly point to IL-13 as a central and indispensable mediator of fibrosis. Therefore, development of an IL-13 antagonist might be a strategy to treat established and progressive disease. Treatment with soluble IL-13Rα_2 has no influence on egg deposition and granuloma formation, but prevents progression of fibrosis (Chiaramonte et al. 2001). In future studies, it will be interesting to combine the beneficial action of IL-13 antagonists with the chemotherapeutic elimination of the parasite for further acceleration of the healing process.

In this context, molecules that inhibit Th2 responses by favoring Th1 development and modulating IL-13 production might also impact on strategies to treat hepatic fibrosis, for example, the chemokine CCL5 has been implicated in contributing to Th1 immune responses while limiting Th2 responses (Chensue et al. 1999). Treatment with recombinant CCL5 reduced type 2 granuloma size by one-third. Therefore, CCL5 may have therapeutic potential in the treatment of established type 2 hypersensitivity.

Another approach focuses on preventing granuloma fibrosis by immunization. Immunization with irradiated larval stages is followed by a protective Th1 immune response that disturbs the migration of the larvae through the lung (Wilson et al. 1999). Sensitization with eggs in the presence of IL-12 dramatically reduces the tissue fibrosis induced by subsequent infection with *S. mansoni* without affecting protective responses (Wynn et al. 1995). This strategy is an example of an immunization that acts by preventing type 2 pathology rather than infection itself.

THE RELATIONSHIP BETWEEN CELL-MEDIATED IMMUNITY AND DELAYED-TYPE HYPERSENSITIVITY

When Mackaness first introduced the concept of the activated macrophage, the temporal coincidence of its appearance with that of the DTH reaction was taken to imply that both were merely two manifestations of the same cellular and molecular processes (Mackaness 1962, 1964) – hence the frequent description of protective immunity as a 'double-edged sword'. Later, it became apparent that, in some instances, acquired resistance could be maintained even in the absence of granulomatous inflammation and that, in other instances, severe DTH-mediated tissue damage could occur in the virtual absence of antibacterial protection. It thus became necessary conceptually to distinguish between protective cell-mediated immunity (CMI) and tissue-damaging DTH. Today, most investigators hold that separate entities (cells and/or mediators) are responsible for macrophage activation versus tissue damage, although the level at which the respective mechanisms are thought to dissociate is open to debate (Table 3).

An opposing opinion argues that the cellular and molecular bases of both CMI and DTH are mostly identical, but are regulated differentially in space and time, particularly in terms of the quantities of cytokines/chemokines secreted and of homing capacities of the cells involved, for example, mice lacking the signature structure on ICAM-1 that allows monocytes to migrate into inflamed lesions were still able to contain mycobacterial growth, but showed significantly reduced granulomatous inflammation early during infection (Johnson et al. 1998). However, when the long-term outcome of infection in ICAM-deficient mice was analyzed, they were found to succumb to elevated bacterial loads because they lacked organized granulomas (Saunders et al. 1999).

In experimental infections with *L. monocytogenes*, it was clearly demonstrated that granuloma formation depends entirely on the $CD4^+$ T-cell subset, whereas the most potent antibacterial protection is conferred by $CD8^+$ T cells, revealing that pathology and protection could be completely dissociated at the level of effector T cells (Mielke et al. 1988, 1992).

In schistosomiasis, the course of immune responses can be separated into a protective Th1 response early after infection and a pathological Th2 immune response characterized by chronic hepatic fibrosis. With respect to crossregulatory mechanisms, promotion of protective Th1 development results in preventing pathological Th2 responses as demonstrated in IL-12-modulated immunization studies (Lukacs et al. 2001). Treatment of an already established Th2 immune reaction reduces granuloma fibrosis without negatively affecting protection. Therefore, IL-13 antagonists represent a promising strategy to treat already established and progressive type 2 DTH-associated pathology.

In *M. tuberculosis* infection, no equally discriminatory basis for macrophage-activating and tissue-damaging pathways has been identified (Ehlers 1999). Rather, the most powerful antibacterially active T cells are of the $CD4^+$ subtype and secrete IFN-γ, as are the most potent DTH-conferring T cells. Similarly, TNF is involved in both antibacterial defense mechanisms and is pivotal during the inflammatory response. It has even been argued that type 1 DTH-associated pathology can have beneficial effects, because it deprives mycobacteria of their intramacrophage habitat and exposes them to life in a hostile environment, i.e. hypoxia, acid pH, and coagulation necrosis (Dannenberg 1968). According to this view, granuloma necrosis would be the ultimate form of antibacterial protection if macrophage activation fails (Dannenberg 1991).

In an attempt at revitalizing the conceptual dissociation of CMI and DTH in TB, it has been proposed that cytokines, such as IFN-γ, might be viewed as mostly involved in protection, whereas chemokines, such as CCL2 or CXCL10, might be considered as mostly associated with the DTH response (Orme and Cooper 1999). Although it is true that chemokines, in their majority, are not known directly to contribute to antibacterial effector mechanisms, cytokines are clearly major players in granuloma formation (TNF, IFN-γ), somewhat invalidating this hypothesis. It is, however, possible that the amplification

Table 3 *Mediators of protection and pathology in Th1 and Th2 responses*

Granuloma type	Cells and mediators	Protection	Pathology

of the inflammatory response, and therefore the excess of inflammation leading to tissue damage, is mostly the result of chemokine secretion. As outlined above, it is becoming increasingly apparent that dissociation between macrophage activation and DTH-associated pathology may exist beyond the level of IFN-γ production. Protective mechanisms induced by IFN-γ (e.g. NOS-2) can clearly be dissociated from necrosis-inducing processes that are IFN-γ dependent, but NOS-2 independent, and that may involve certain chemokines. The latter therefore represent attractive targets for therapeutic immunointervention aimed at harnessing tissue-damaging pathways without compromising antibacterial protection.

Airway hypersensitivity

ELIZABETH R. JARMAN AND JONATHAN R. LAMB

Introduction	1	Immunoregulatory networks	8
Immunological mechanisms underlying the asthmatic phenotype	2	Conclusions	11
Association between innate and adaptive immunity in the induction of AHR	7	References	11

INTRODUCTION

Airway hyperresponsiveness is a prominent feature of a variety of pulmonary diseases, although it is most often associated with asthma. Asthma is a complex disease of the airways associated with bronchial inflammation, reversible airway obstruction, mucus hypersecretion, and hypersensitivity (increased bronchial reactivity to nonspecific spasmogenic stimuli), defined as airway hyperresponsiveness (AHR). In people with chronic asthma these processes culminate in irreversible changes in airway physiology. There has been a marked increase in the prevalence of asthma in the last few decades. Although there is undoubtedly a genetic component underlying the predisposition toward onset of disease, the scale of the increase in the developed world suggests that environmental factors associated with changes in lifestyle and an improvement in the standard of living must also play a role. Asthma is polygenic and multifactoral in origin and is often classified as intrinsic (antigen independent) or extrinsic (allergic) asthma. Allergic asthma is triggered by antigen-specific exposure to common environmental aeroallergens, such as those present in grass or tree pollen, animal dander, or house dust mites. The aim of this chapter is to review our current understanding of the immunological mechanisms underlying asthma and AHR in the light of recent studies that suggest that the increasing prevalence of asthma may be the result of a loss of inherent immunoregulatory mechanisms.

Airway hyperreactivity

The mechanisms underlying the development of AHR are not fully understood. It is thought to arise as a result of successive inflammatory processes in the airway mucosa triggered by respiratory infections or repeated exposure of susceptible individuals to aeroallergens, resulting in the induction of T-helper (Th)2 cytokines, which play both a direct role in the induction of AHR, as well as an indirect role associated with tissue damage caused by the release of inflammatory mediators from effector cells such as eosinophils recruited into the airways after allergen exposure (Holt et al. 1999). Pathophysiological changes in the airways resulting from chronic inflammation, compounded by altered neural regulation of airway tone, are thought to contribute toward AHR. Increased deposition of extracellular matrix (ECM) proteins in the airway submucosa, increased vascularity, and tissue edema, as well as an increase in airway smooth muscle mass (ASM), lead to thickening of the airway wall and exaggerated airway narrowing in response to various stimuli. A number of mediators released during the inflammatory response are though to contribute toward increased ASM. Histamine, platelet-activating factor (PAF), and the leukotrienes (LT), released from mast cells and eosinophils, are potent inducers of increased bronchial permeability, thereby contributing directly to bronchial edema. The injured airway epithelial cell (AEC) is also a potent source of a number of cytokines, chemokines, and

inflammatory mediators, thereby contributing toward AHR and airway remodeling (Holgate 1998).

Early acute phase response

Mast cells are essential for the IgE-dependent, immediate hypersensitivity acute phase reaction to aeroallergens. Within minutes of allergen exposure, cross-linking by multivalent allergen of preformed IgE bound to the high-affinity IgE receptor (FcεRI) on mast cells results in an immediate hypersensitivity reaction, characterized by the release of the preformed mediators histamine and the proteases (tryptase and chymase), cytokine transcription, and the de novo synthesis and secretion of the cyclooxygenase and lipoxygenase metabolites of arachidonic acid, prostaglandin D_2 (PGD_2), and leukotriene C_4 (LTC_4). These inflammatory mediators activate inflammatory effector cells, and cause mucus secretion, smooth muscle constriction, and increased vascular permeability, thereby potentiating airway inflammation and AHR.

Late phase response

The late phase response (LHR) is associated with the eosinophil recruitment, activation and release of the eosinophil-derived inflammatory mediators, eosinophil cationic protein (ECP), major basic protein (MBP), and eosinophil derived neurotoxin (EDN), in addition to leukotrienes, prostaglandins, particularly PGD_2, and PAF. Eosinophils are also a source of a number of cytokines, including the eosinophil activation and survival factor, IL-5, as well as the profibrotic factor transforming growth factor β (TGF-β). There is a close association between pulmonary eosinophilia and AHR in both extrinsic and intrinsic (nonatopic) asthma. Elevated levels of ECP and MBP have been detected in the bronchoalveolar lavage (BAL) of patients with asthma. These proteins can induce AHR as a direct consequence of their damaging effect on the airway epithelium (Wardlow et al. 1988).

Airway remodeling

Airway remodeling and the resulting structural changes are features of chronic asthma, observed in both atopic and nonatopic individuals. Although the inflammatory response associated with both forms of asthma is characterized by the presence of Th2 cytokines, the existence of a specific IgE is not a prerequisite for the development of asthma, which suggests that abnormalities in the airway epithelium, which forms a barrier to the external environment, results in sensitization to allergens and subsequent development of the asthmatic phenotype. This process may be facilitated by exposure to pathogens such as respiratory viruses, or irritants, which further damage the epithelium. In chronic asthma, structural changes in the bronchial epithelium arise as a result of increased collagen deposition beneath the basal lamina with thickening of the basement membrane, goblet cell hyperplasia, and increased mucin production. These changes eventually lead to irreversible airway obstruction, and a reduction in airway function associated with increased bronchial hyperresponsiveness. Increases in mucus production and goblet cell hyperplasia are common features in cases of fatal asthma (Aikawa et al. 1992).

In asthma, products released by mast cells and eosinophils are directly responsible for damage to the epithelium. The interleukin cytokines IL-4, IL-5, IL-9, and IL-13 released by Th2 effector cells are responsible for many of the features of airway remodeling. Goblet cell metaplasia and mucus production are associated with IL-4- and IL-13-induced increases in expression of the genes *muc5ac*, *muc2*, and *muc4* which are detected in bronchial biopsies obtained from people with asthma. Overproduction of IL-4 in the lung induces *muc5ac* gene expression and mucus secretion by airway epithelial cells expressing the common IL-4Rα chain (Temann et al. 1997), and is dependent on STAT6 signaling (Kuperman et al. 1998). The immunoregulatory molecules TGF-β, and more recently IL-10, have been shown in independent studies to induce subepithelial fibrosis, suggesting that certain aspects of airway remodeling may be an undesirable consequence of an attempt to downregulate chronic inflammatory responses (Elias et al. 1999; Lee et al. 2002)

IMMUNOLOGICAL MECHANISMS UNDERLYING THE ASTHMATIC PHENOTYPE

IgE-mediated pathology in asthma and AHR

Genetic linkage studies have identified an association between chromosome 5q and two of the principal features of allergic asthma: total serum IgE levels and bronchial hyperresponsiveness (Marsh et al. 1994; Postma et al. 1995). A number of clinical studies have demonstrated that elevated specific IgE levels in sera are associated with asthma. Whether this reflects the location on chromosome 5q of the cytokines IL-4 and IL-13, which are directly responsible for increased airway hyperresponsiveness, as well as the switch to ϵ germline transcription and IgE synthesis by B cells (Oettgen and Geha 2001), or an essential role for IgE in the initiation of asthmatic responses is disputed. A recent study carried out on a cohort of Australian families concluded that, of the multiple genetic traits that were found to contribute toward the pathophysiology of asthma, the two dominant traits, namely increased serum IgE levels

and AHR, were clearly independently inherited (Palmer et al. 2000). Numerous clinical studies have demonstrated that increased serum IgE, although associated with allergic disease, does not necessarily predispose toward development of asthma and AHR (Sunyer et al. 1995). Most studies in murine models of allergic asthma have shown that AHR can be induced in the absence of B cells or specific IgE antibodies (Mehlhop et al. 1997; Hogan et al. 1997; Hamelmann et al. 1997, 1999).

Nevertheless, allergic sensitization to allergens and IgE-mediated responses play a significant role in the development of asthma in a large number of patients. Specific IgE contributes towards the clinical phenotype by inducing mast cell degranulation and release of inflammatory mediators, following crosslinking of the high-affinity FcεR. Mediators released from mast cells trigger a cascade of events which culminate in asthma and increased AHR. Recently, completed phase II clinical trials have shown that patients with severe asthma, who are known to respond poorly to steroid treatment, demonstrated a marked improvement in symptoms after treatment with a humanized anti-IgE monoclonal antibodies (McAbs). Anti-IgE McAbs are thought to act by binding to and neutralizing circulating IgE antibodies, thereby preventing them from binding to FcεRs (Bush 2002; Lemanske et al. 2002).

Mechanisms of $CD4^+$ Th2 cytokine-induced pathology in asthma and AHR

Asthma is a chronic inflammatory disorder that can eventually lead to structural changes in the airways, arising as a result of increased collagen deposition, smooth muscle proliferation, and mucus hyperplasia which cause bronchial hyperresponsiveness and variable airflow obstruction. In both allergic and intrinsic asthma, the inflammatory response is associated with the recruitment of activated $CD4^+$ T lymphocytes expressing a Th2 cytokine profile (Ying et al. 1997a), and an influx of eosinophils. The interleukins, IL-4, IL-5, IL-9, and IL-13, expressed by activated $CD4^+$ Th2 cells which are the dominant cell type in bronchoscopic biopsies and BAL samples obtained from patients with asthma, are thought to play a central role in the pathophysiology of asthma (Robinson et al. 1992).

Genetic linkage studies identified an association with asthma and related traits in the region of chromosome 5q, in which the IL-4, IL-5, IL-9, and IL-13 genes are clustered (Marsh et al. 1994; Postma et al. 1995), and a region of chromosome 16p12 in which the gene encoding the IL-4Rα chain is located (Hershey et al. 1997). Multiple polymorphisms have been identified within the IL-13 gene and IL-4R gene complex, which reassociated with asthma (Heinzmann et al. 2000; Ober et al. 2000).

There is considerable functional redundancy among these pleiotropic Th2-derived cytokines in asthma. For this reason, their relative importance in the development of AHR is still not fully defined. Temporal differences in the kinetics of cytokine expression and in the distribution of their receptor molecules will determine the contribution of these cytokines toward the asthmatic response. It has proved difficult to establish the respective roles of the Th2-derived cytokines IL-4 and IL-13. These cytokines exhibit partially overlapping effector profiles as a result of their common use of the IL-4 receptor α chain (IL-4Rα) as the signaling component within the multimeric IL-4 and IL-13 receptor complexes. The IL-4 R consists of the IL-4Rα chain and the common γ chain (of the IL-2 receptor). The functional IL-13 receptor complex is a heterodimer consisting of the IL-13Rα1 chain which interacts with either the IL-4Rα chain or the IL-13Rα2 chain. Signaling through the IL-4Rα chain leads to activation of the Janus kinase family of tyrosine kinases, resulting in the recruitment, phosphorylation, and nuclear translocation of the transcription factor signal transducer and activator of transcription 6 (STAT6) (Shirakawa et al. 2000). The importance of the STAT6 signaling pathway in the induction of airway eosinophilia and increased AHR was demonstrated in STAT6-deficient mice. These mice failed to develop specific IgE antibodies, airway eosinophilia, or AHR on exposure to methylcholine, after sensitization and challenge of the airways with allergens. Mucus production was significantly reduced compared with wild-type animals (Akimoto et al. 1998; Kuperman et al. 1998).

Using selected lines of Th2 cytokine-deficient mice, deficient in single or multiple cytokine genes, it has been possible to demonstrate that, although IL-5, IL-9, and IL-13 all contribute toward the magnitude of the inflammatory response, IL-4 is essential for initial activation of Th2 effector functions (Fallon et al. 2002). IL-4 is critical for the induction of Th2 responses to allergen, but is not essential for the development of late-phase airway inflammation and AHR. AHR can be induced in naïve mice after adaptive transfer of antigen-specific $CD4^+$ Th2 cells obtained from IL-4-deficient mice (Coyle et al. 1995; Cohn et al. 1998). Although not essential, IL-4 enhances a number of STAT6-dependent responses in the airways which contribute toward AHR. These include enhanced mucus production through the induction of *muc5ac* gene expression by epithelial cells in the airways, release of the eosinophil chemoattractant eotaxin, and upregulation of VCAM-1 expression on endothelial cells, thereby promoting increased recruitment of lymphocytes and eosinophils (Nakajima et al. 1994; Rankin et al. 1996; Temann et al. 1997; Mocjizuki et al. 1998).

The pleiotrophic Th2-derived interleukin IL-13 is now recognized as being largely responsible for initiating and maintaining many of the functions associated with the late-phase inflammatory response, which result in altered airway physiology and remodeling, including

goblet cell hyperplasia with mucus hypersecretion and AHR. Notably, both these features of the asthmatic response are commonly associated with asphyxiation (Aikawa et al. 1992). IL-13 also exhibits a number of effects that are responsible for enhancing the IgE-mediated acute phase response, including induction of IgE production by B cells and upregulation of CD23 (FcεRII) expression on B cells, and the upregulation of the expression of the integrin vascular adhesion molecule VCAM-1 on endothelial cells (Zurawski and de Vries 1994; Bochner et al. 1995; Emson et al. 1998). Instillation of IL-13 into the lungs of naïve mice was sufficient to induce many of the features of asthma, including elevated serum IgE, airway eosinophilia, increased mucus production, and AHR. The central role of IL-13 as a mediator in asthma was demonstrated by inhibiting its activity through the administration of the soluble IL-13Rα_2-IgGFc fusion protein, to sensitized and challenged mice, before secondary exposure to allergen via the airways. These mice exhibited attenuated goblet cell hyperplasia, mucus production, and AHR on challenge with a spasmogenic agent, despite detectable airway eosinophilia and normal IgE levels (Wills-Karp et al. 1998).

The independence of IL-13-mediated AHR in the airways on T-cell-driven airway inflammation and IgE production was demonstrated in RAG-1$^{-/-}$-deficient mice, which lack T and B lymphocytes, indicating that IL-13 mediates its effects though direct activation of cells in the airways (Grunig et al. 1998). This view was confirmed in subsequent studies, which demonstrated that IL-13 is not only necessary but also sufficient for the induction of AHR. The failure of mice deficient in either IL-13 or IL-4 and IL-13 to develop AHR in spite of increases in IL-5-mediated airway eosinophilia, after sensitization and challenge with allergen, could be reversed by the instillation of recombinant IL-13 alone into the airways (Walter et al. 2001). Chronic expression of IL-13 in the airways was sufficient to cause enhanced recruitment of lymphocytes, eosinophils, and macrophages into the airways, together with subepithelial fibrosis, upregulation of mucin (*Muc5ac*) gene expression, and mucus hypersecretion and increased AHR (Zhu et al. 1999). Increases in both mucus hypersecretion and AHR were mediated by IL-13 through STAT6-dependent mechanisms (Kuperman et al. 2002). However, increases in AHR were also observed in IL-4Rα chain-deficient mice constitutively expressing IL-13 in the airways, or after transfer of IL-13-producing, antigen-specific, CD4$^+$ T cells, indicating that separate components of the STAT6-dependent signaling pathway were involved (Mattes et al. 2001). In addition to its direct effect on airway epithelial cells, IL-13 may influence AHR through direct effects on airway smooth muscle and activation of fibroblasts, resulting in altered deposition of matrix proteins.

IL-13-mediated recruitment and activation of CD4$^+$ Th2 lymphocyte and eosinophils in the airways during the inflammatory response also contribute toward AHR. The coordinated temporal and site-directed expression of chemokines and chemokine receptors is central to the complex pathophysiology of asthma. Elevated levels of the CC chemokines, eotaxin, eotaxin-2, RANTES (monocyte chemotactic protein (MCP)-1, -3. and -4 and the chemokine receptor CCR3 expressed on mast cells, basophils, and eosinophilis, as well as CD4$^+$ Th2 lymphocytes and myeloid dendritic cells (DC), have been observed in the lungs of patients with allergic asthma (Ying et al. 1999). IL-13 is a potent inducer of a number of chemokines involved in the development of the asthmatic phenotype. Levels of mRNA for these chemokines were increased in the lungs of CC10-IL-13 transgenic mice, which selectively overexpress the IL-13 transgene in the airways. Many of the inflammatory and profibrotic effects of IL-13 are mediated through the induction of chemokines responsible for the recruitment of inflammatory cells into the airways. IL-13 is a potent inducer of eotaxin expression by airway epithelial cells (Li et al. 1999), which is a principal chemoattractant for eosinophils, and CCR3 expressing CD4$^+$ Th2 lymphocytes during the initiation of airway inflammation. IL-13-induced increases in production of monocyte-derived chemokine (MDC) and MCP-1, the respective ligands for CCR4 expressed on activated CD4$^+$ Th2 cells and CCR2 expressed on macrophages, are thought to enhance recruitment of these cells into the airways. The importance of the coordinated expression of these chemokines in the induction of airway inflammation and remodeling that results in AHR has been demonstrated in murine models of asthma. Neutralization of MDC activity by the use of specific antibodies lead to reductions in CD4$^+$ T lymphocytes recruited from the airway lumen into the lung, which correlated with attenuated AHR (Gonzalo et al. 1999). The enhanced airway inflammation and tissue fibrosis, observed in CC10-IL-13 transgenic mice, were greatly reduced in mice deficient in CCR2 (Zhou et al. 2002). By inducing increased production of MCP-1, the ligand for CCR2, IL-13 drives the recruitment of macrophages into the airways, where they are though to initiate subepithelial fibrosis, through production of the profibrotic factor TGF-β_1 (Lee et al. 2001). These studies indicate that IL-13, through the induction of eotaxin, MDC, and MCP-1, indirectly regulate Th2-mediated airway inflammation, eosinophilia, and tissue fibrosis, respectively.

The central role played by IL-13 in the pathology associated with pulmonary inflammation and fibrosis is not restricted to asthma, and has been observed in a number of respiratory diseases including respiratory syncytial virus infection, fungal pneumonitis, and chronic obstructive pulmonary disease (Lukacs et al. 2001; Blease et al. 2000). Alveolar macrophages in the airways may be the initial source of IL-13 in pulmonary inflam-

matory disease (Prieto et al. 2000), with relative levels of IL-12 and IL-13 production by macrophages in the airways during primary antigen challenge influencing the phenotype of effector T cells.

Levels of the Th2-derived cytokine IL-9 and expression of the IL-9R are elevated in the lungs of patients with allergic asthma (Shimbara et al. 2000). IL-9 stimulates a number of different cell types, including B cells, mast cells, eosinophils, and airway epithelial cells, leading to the development of a number of features that are characteristic of asthma and AHR (Petit-Frere et al. 1993; Longphre et al. 1999; Gounni et al. 2000; Louahed et al. 2001). Transgenic mice exhibiting either constitutive or inducible IL-9 expression in the lung have many of the features associated with asthma, including eosinophilic and lymphocytic infiltration of the airways, mucus hypersecretion, subepithelial fibrosis, mast cell hyperplasia, and AHR (Tenmann et al. 1998). The effects mediated by IL-9 may be the result of increased expression of the Th2 cytokines IL-4, IL-5, and IL-13 in the lungs of IL-9 transgenic mice. Neutralization of IL-13 completely abolished both lung inflammation and mucus production (Tenmann et al. 2002), indicating that expression of IL-9 alone is insufficient to induce pathological changes associated with asthma and that these cytokines are required to act in combination in order to achieve optimal stimulation. The unique role of IL-13 in the induction of AHR is most probably the result of its direct effects on airway epithelial cells, mediated independently of the common IL-4Rα chain.

The role of mast cells in the induction of AHR

Mast cells are important in initiating and amplifying the IgE-mediated acute hypersensitivity response to allergens. Crosslinking of FcεRs by IgE–allergen complexes causes degranulation and release of inflammatory mediators such as histamine, prostaglandin (PGD_2) and the leukotrienes (LTC_4) which trigger bronchoconstriction in the asthmatic lung (Metcalf et al. 1997; Matsuoka et al. 2000). As a major primary source of IL-4 in the lungs, mast cells and tissue basophils may also play an important role in priming Th2 responses in the airways (Nouri et al. 2001). A number of cytokines (TNF-γ, IL-1, IL-3, granulocyte–macrophage colony-stimulating factor (GM-CSF), IL-4, IL-5, IL-6, and IL-8) and chemokines (MCP-1, macrophage inflammatory protein 1α [MIP-1α], MIP-1β, and eotaxin), expressed by mast cells are important for the recruitment and activation of effector cells, including eosinophilis, which are involved in the late phase response (Das et al. 1998). Nevertheless, studies in mast cell-deficient $Kit^{w}/Kit^{w\text{-}v}$ mice indicate that many features of the late phase response, including eosinophilia and AHR, can occur in the absence of mast cells, suggesting that there is considerable redundancy in the mechanisms contributing toward the allergic response (Takeda et al. 1997). Studies in animal models of asthma indicate that, at low concentrations of allergen exposure, mast cells play a prominent role in the induction of IgE-mediated AHR (Kobayashi et al. 2000). Binding of IgE to the FcεRI on mast cells induces the upregulation of FcεRI, thereby enhancing IgE-dependent release of inflammatory mediators even at low levels of allergen exposure (Yamaguchi et al. 1999). Furthermore, binding of monomeric IgE to the FcεRI on mast cells inhibits apoptotic signals, thereby enhancing survival of mast cells in the airways and leading to further amplification of the asthmatic response (Asai et al. 2001).

The role of eosinophils in the induction of AHR

Eosinophils are considered to be the major effector cells in the pathogenesis of the late phase asthmatic response and consequently of AHR. Inflammatory mediators released from their granules, in particular the leukotrienes, can lead to damage of the airway epithelium resulting in AHR (Gleich et al. 1993). Some, but not all clinical studies (McFadden 1994) have observed a correlation between eosinophil levels in BAL and bronchial biopsies obtained from allergic patients, and disease severity as assessed by AHR (Wardlow et al. 1988). There are considerable clinical data that support the view that disease severity in asthma directly correlates with IL-5 and eosinophil levels (Bentley et al. 1993; Sur et al. 1995). The Th2-derived cytokine IL-5 is a key regulator of airway eosinophilia, acting as both a growth factor and a chemoattractant to induce differentiation, activation, recruitment, and survival at sites of allergen exposure (Lopez et al. 1988). Nevertheless, the role of IL-5-dependent airway eosinophilia in the induction of AHR has not been fully clarified. A recent clinical trial performed using a humanized McAb raised against IL-5 revealed that, despite attenuating eosinophil recruitment into the airways, there was no resolution of AHR in patients (Leckie et al. 2000).

Animal models of pulmonary inflammation have provided some insight into the role of eosinophils in the induction of AHR. Increased levels of eosinophils in the airways are associated with AHR (Tomkinson et al. 1999) and AHR can occur independently of the presence of both IL-5 and eosinophils (Corry et al. 1996). However, treatment of sensitized mice with anti-IL-5-neutralizing antibodies before allergen challenge of the airways, while having no effect on early acute phase responses, abolished late-phase inflammatory responses, with a loss of both airway inflammation and AHR (Foster et al. 1996; Hamelmann et al. 1999). STAT6 is essential for many IL-4- and IL-13-mediated responses which impact on the levels of AHR (Kaplan et al. 1996).

Therefore, the ability to induce not only airway eosinophilia, but also AHR on exposure of STAT6-deficient mice to allergen by reconstitution with IL-5 indicates that eosinophilis are sufficient to induce AHR in the absence of specific IgE, mucus production, or Th2 effector cells (Tomkinson et al. 1999). These discrepancies in the data may partially reflect genetic differences between the inbred strains of mice used, which could influence susceptibility to AHR (Wilder et al. 1999; Ewart et al. 2000).

Data obtained from animal models of disease have been interpreted on the assumption that IL-5 is principally responsible for airway eosinophilia. For this reason, studies investigating the role of eosinophils in the induction of AHR have focused primarily on the use of IL-5-deficient mice or IL-5-neutralizing antibodies and have indicated that neutralization of IL-5 is insufficient to abrogate airway eosinophilia. In addition to IL-5, the chemokine eotaxin acts as a major chemoattractant not only for eosinophils, but also for activated $CD4^+$ Th2 cells expressing the CCR3 chemokine receptor (Sallusto et al. 1997). CCR3 is the receptor for a number of chemokines associated with Th2-mediated airway inflammation in asthma, including eotaxin, and appears to be essential for the recruitment of both eosinophils and $CD4^+$ Th2 cells and in the induction of AHR (Lloyd et al. 2000; Ma et al. 2002). Analysis of bronchial biopsies from patients with asthma revealed that the intensity of eotaxin and CCR3 mRNA expression correlated with increased AHR (Ying et al. 1997b). Interestingly, the Th2-derived cytokine IL-13 can also upregulate eotaxin production by residual cells in the airways, including smooth muscle, fibroblasts, and airway epithelial cells, thereby contributing indirectly to tissue eosinophilia (Matsukura et al. 2001; Hirst et al. 2002; Wenzel et al. 2002). Binding of the very-late-activating antigen 4 (VLA-4), expressed on both eosinophils and T cells, to VCAM-1 expressed on the surface of endothelial cells is essential for cellular recruitment into the airways. Attenuation of both airway eosinophilia and AHR, by administration of neutralizing antibodies raised against IL-5 or VLA-4 to sensitized mice immediately before challenge of the airways with allergen, suggests a potentially independent role for $CD4^+$ Th2 effector cells and eosinophils in the induction of AHR (Tomkinson et al. 2001).

Although eosinophils undoubtedly play a prominent role in contributing toward bronchial hyperreactivity, there is considerable evidence that AHR can be induced in their absence. Th2 cells are not only responsible for initiating airway inflammation and eosinophilia but are also directly responsible for inducing AHR through production of cytokines, notably IL-13. This has been clearly demonstrated in STAT6-deficient mice in which the transfer of $CD4^+$ T cells from sensitized mice was sufficient to induce AHR on challenge of the airways with allergen, even in the absence of eosinophilia (Tomkinson et al. 2002). Nevertheless, it is likely that eosinophils contribute toward the induction of AHR, not only as effector cells through their ability to release inflammatory mediators, but also through the induction of Th2 responses. Studies by Mattes et al. (2002) have demonstrated that mice deficient in both IL-5 and eotaxin failed to develop airway eosinophilia and AHR on allergen exposure, and furthermore that $CD4^+$ Th2 cells isolated from these mice were impaired in their ability to produce IL-13, which is directly responsible for the induction of AHR. Transfer of eosinophils from wild-type mice was sufficient to re-establish IL-13 production by $CD4^+$ Th2 effector cells, supporting evidence that eosinophils, acting as antigen-presenting cells, have the potential to promote Th2-dependent responses in the asthmatic airways. Eosinophils isolated from the airways of patients with allergic asthma exhibited elevated levels of MHC class II and the costimulatory molecules CD80 and CD86 (MacKenzie et al. 2001). Furthermore, on exposure to allergen, eosinophils migrate from the airways to the T-cell-rich paracortical zones of draining lymph nodes, where antigen presentation takes place (Shi et al. 2000). It is likely that multiple factors acting either independently or in concert contribute toward AHR. $CD4^+$ Th2 cells are central for the induction of airway inflammation and eosinophilia, and it is therefore likely that they contribute, through the cytokines that they release, both directly and indirectly to AHR. As a major source of both IL-5 and IL-13 (Schmid-Grendelmeier et al. 2002), eosinophils may play a role in amplifying the inflammatory response, leading to chronic airway inflammation, enhanced bronchoconstriction, and AHR.

Antigen-presenting cells in the mucosal surfaces of the airways and their role in the induction of asthma

Dendritic cells are professional antigen-presenting cells that form a dense network in the airways lining the nasal and bronchial mucosa and lung interstitium (Holt et al. 1989). These cells are, therefore, ideally placed to sample antigen, which is then processed and presented to naïve T cells, following migration of DCs to the lymph nodes draining the airways (Vermaelen et al. 2001). Studies in animal models demonstrate that DCs play a critical role not only in the induction of $CD4^+$ Th2 cell-mediated responses and IgE synthesis, but also in maintaining late phase responses in sensitized animals, including airway eosinophilia and goblet cell hyperplasia (Lambrecht et al. 1988). Studies in patients with allergic asthma showed that $CD11c^+$ $HLA\text{-}DR^+$ DCs are rapidly recruited to the airways within hours of allergen exposure (Jahnsen et al. 2001). Independent studies have reported that the number of circulating $CD33^+$ DCs in the peripheral blood of patients with

asthma is reduced after allergen exposure (Upham et al. 2002). Evidence for expression of the receptor for the chemokine eotaxin, CCR3, by $CD34^+$ human DCs of the myeloid lineage suggests that these cells are recruited into the airways of people with asthma after upregulation of eotaxin, where they may play a role in maintaining Th2-mediated inflammatory responses (Beaulieu et al. 2002). Recent studies demonstrated that $CD11c^+$ $CD11b^+$ myeloid DCs in the airways are capable of retaining antigen for prolonged periods of time and, furthermore, that these cells are primarily responsible for presenting antigen to effector T cells in the lung (Julia et al. 2002). The presence of specific IgE bound to the high-affinity FcεRI on DCs in the periphery and the bronchial mucosa could potentially lower the activation threshold, thereby increasing responsiveness at low levels of allergen exposure (Tunon de Lara et al. 1996; Holloway et al. 2001). These data suggest that DCs are essential not only for initiating the T-cell-mediated, late phase response to allergens, but also for maintaining low levels of chronic inflammation, which could ultimately lead to airway remodeling.

The airway mucosa is continually exposed to common nonpathogenic environmental antigens. It is, therefore, likely that mechanisms have evolved for maintaining homeostasis, thereby preventing the induction of inappropriate inflammatory responses in the airways. The dramatic increase in the incidence of atopic asthma in the developed world, which has coincided with an increase in auotoimmune diseases, may reflect a loss of inherent immunoregulatory mechanisms. IL-10 is an immunoregulatory cytokine that is produced by a number of cell types and has a wide range of immunosuppressive effects including inhibition of DC maturation and macrophage activation, downregulation of leukocyte adhesion molecule expression, and suppression of T-cell proliferation and Th1 cytokine production (Moore et al. 2001). IL-10 has recently been described as a growth factor for a subset of $CD4^+$ $CD25^+$ T-regulatory cells, which are thought to be central to the induction and maintenance of immunological tolerance to selfantigens, thereby preventing the onset of autoimmune disease (Groux et al. 1997).

Dendritic cells in the airways, through their role in sampling antigen from the environment and their unique ability to prime naïve T-cell responses, may play a determining role in the induction of tolerance and immune regulation on exposure to allergens. In the absence of infection or inflammatory stimuli, DCs retain an immature phenotype. The presentation of antigen to naïve T cells by immature DCs would hypothetically result in T-cell-receptor ligation in the absence of costimulation, leading to the induction of a state of tolerance (Mueller et al. 1989). A direct role for pulmonary DCs in the induction of mucosal tolerance to inhaled antigen has been demonstrated in vivo. DCs isolated from the bronchial lymph nodes draining the lungs of mice exposed via the nasal mucosa to soluble antigen, in the absence of inflammatory stimuli, were able to adoptively transfer a state of antigen-specific tolerance to naïve mice. By repeating these studies in IL-10 knock-out mice, the authors were able to demonstrate that the expression of a tolerogenic pheonotype by DCs was dependent on the presence of IL-10. Furthermore, they found that, by culturing antigen-specific $CD4^+$ T cells with these IL-10-producing pulmonary DCs, they were able to induce a $CD4^+$ T regulatory cell-like phenotype as associated with IL-10 production (Akbari et al. 2001).

In the presence of pathogen-derived inflammatory stimuli, DCs undergo maturation and upregulation of the chemokine receptor CCR7, which facilitates migration to lymph nodes where DCs, which have acquired potent antigen-presenting capacity afer upregulation of MHCII molecules and the costimulatory molecules CD80 and CD86, prime T-cell responses. In vitro studies have demonstrated that autocrine IL-10 can suppress DC maturation in response to stimulation with lipopolysaccharide (LPS), or soluble CD40 ligand, thereby inducing a tolerogenic phenotype (Corinti et al. 2001; Steinbrink et al. 1997). Furthermore, the ability of IL-10 to inhibit upregulation of the chemokine receptor CCR7 on stimulated DCs could prevent DCs from migrating to the draining lymph nodes, where antigen presentation and T-cell priming would normally take place (D'Amico et al. 2000). Studies using labeled T cells demonstrated that primed effector T cells that had migrated to the airways, although being capable of producing cytokines and inducing eosinophilia, failed to proliferate on exposure to antigen (Harris et al. 2002). As effector $CD4^+$ T cells have lost their capacity to migrate out of peripheral tissues, continued priming of effector memory T-cell populations by DCs in the lymph nodes may be necessary in order to maintain a chronic asthmatic state. Production of IL-10 within the airways at the time of allergen challenge may play a role in limiting the inflammatory asthmatic response.

ASSOCIATION BETWEEN INNATE AND ADAPTIVE IMMUNITY IN THE INDUCTION OF AHR

Immunoregulatory mechanisms of γδ T cells in maintaining homeostasis in the airways

Intraepithelial γδ T cells, which are located in the mucosal surfaces of the airways, may be involved in maintaining homeostasis on exposure to inflammatory stimuli, thus protecting against pathological processes culminating in bronchoconstriction and AHR. Mice genetically deficient in γδ T cells (T-cell receptor (TCR)-$\delta^{-/-}$) exhibited elevated levels of AHR on exposure to methylcholine following sensitization and chal-

lenge with allergen. No increases in immunoglobulins, Th2-derived cytokines, or eosinophil levels were observed, indicating that γδ T cells exert their regulatory function through antigen-independent mechanisms, most probably involving a direct interaction with neighboring airway epithelial cells, thereby inhibiting the release of proinflammatory cytokines and chemokines (Lahn et al. 1999). By promoting clearance of necrotic tissue in the airways, γδ T cells may also play a role in limiting pulmonary injury (King et al. 1999).

Complement factors

Epidemiological studies indicate an association between exposure to particulate matter in air pollutants and exacerbation of bronchoconstriction, leading to increased AHR (Dockery and Pope 1994). This view is supported by data obtained from animal studies, demonstrating an increase in AHR on exposure to particulate matter in diesel fumes (Ohta et al. 1999). Activation of the complement pathway, resulting in cleavage of complement factors C3 and C5 and release of the anaphylotoxins C3a and C5a, is an integral part of the innate immune response to mucosal infection. Their receptors, C5aR and C3aR, are constitutively expressed on bronchial epithelial cells, AECs, smooth muscle cells, and vascular endothelial cells (Drouin et al. 2001). Many of the features of asthma, including smooth muscle contraction, mucus secretion, increased vascular permeability, as well as the recruitment and activation of inflammatory cells, can be mediated by the actions of these anaphylotoxins. C3a is a chemoattractant and activation factor for mast cells and eosinophils. Patients with allergic asthma exhibit increased levels of C3 in the BAL fluid and upregulated expression of C3aR on airway smooth muscle cells shortly after exposure to allergen. Furthermore, mice deficient in C3 or the C3aR fail to develop AHR on sensitization and exposure to allergen, despite exhibiting Th2-mediated airway eosinophilia and increased IgE production (Humbles et al. 2000). Exposure to particulate matter was sufficient to induce AHR in wild-type, but not C3-deficient, mice (Walters et al. 2002). Increases in air pollution may, therefore, account for the rise in both extrinsic and intrinsic asthma, assuming that the complement pathway acts as an antigen-independent link between the innate and adaptive immune response. Interestingly, the gene-encoding complement factor 5 (C5) has been identified as a susceptibility locus for allergen-induced AHR in mice. Studies suggest that C5-mediated responses may protect against the development of Th2-dependent increases in AHR. Blockage of C5a receptor-mediated signaling using a C5aR antagonist inhibited the production of the Th1-promoting cytokine IL-12 by human monocytes stimulated with *Staphylococcus aureus* and furthermore reversed IFN-γ-mediated suppression of IL-10 production (Karp et al. 2000).

IMMUNOREGULATORY NETWORKS

The immunological basis for the hygiene hypothesis

There is increasing evidence that the development of allergic asthma after sensitization to allergen is a consequence of the interaction between environmental factors and the genetic background of that individual. The prevalence of asthma has increased most markedly in the developed world. Although increased pollution and exposure to indoor allergens were originally proposed to account for this increase, epidemiological studies found that asthma prevalence was lower in former East Germany, in spite of high levels of pollution, than in the cleaner more affluent former West Germany (Nicolai and von Mutius 1997). In contrast, epidemiological and immunological data appear to support the 'hygiene hypothesis', which proposes that the increase in the prevalence of asthma is the result of a reduction in childhood infections. The study performed by von Mutius is of particular interest, because it draws attention to the possible role of the bacterial product endotoxin, a LPS found in the outer wall of gram-negative bacteria, in shaping the immune response. This study demonstrated that children raised in rural areas and heavily exposed to farm animals were less likely to develop allergy and asthma than children who had grown up in the same environment but were not exposed to farm animals. Natural exposure to environmental endotoxins in the stables appeared to protect children from developing allergies (Von Mutius et al. 2000). Epidemiological studies provide some support for this hypothesis. An inverse correlation was observed between positive DTH responses to tuberculin and the development of atopy (Shirakawa et al. 1997). Separate studies indicate that early immunization with mycobacteria BCG protects against the development of allergic disease (Aaby et al. 2000).

Studies in animal models of allergic asthma have demonstrated that pretreatment with the BCG before sensitization protects against the subsequent induction of Th2-mediated IgE production, airway eosinophilia, and increased AHR. Protection correlated with increased antigen-specific Th1 immunity and IFN-γ production (Erb et al. 1998; Hertz et al. 1998). Furthermore, administration of mycobacterial antigens to previously sensitized animals attenuated the late phase inflammatory responses and AHR, although IgE levels in serum and early acute phase reactions were not affected (Hopfenspirger and Agrawal 2002). The protective effect of mycobacteria is thought to arise through the induction of IL-12 and IFN-γ resulting in enhanced Th1 immunity,

which counterbalances the Th2 response to allergens. Mucosal gene transfer of IFN-γ directly into the airways of sensitized mice significantly inhibits the induction of Th2-mediated airway eosinophilia and AHR on exposure to allergen (Li et al. 1996). Nevertheless, data obtained from a number of independent studies indicates that IFN-γ-dependent Th1 responses may not only fail to counterbalance Th2-mediated immunity, but may also actually exacerbate the ongoing inflammatory response (Hansen et al. 1999).

Mycobacteria may protect against the induction of the Th2-mediated inflammatory response to allergens, by initiating a number of immunoregulatory mechanisms. Mycobacteria are known to stimulate the innate immune response, leading to enhanced levels of IL-12 and IFN-γ production by antigen-presenting cells including DCs, macrophages, and natural killer (NK) cells. Mycobacterially derived heat shock proteins have been shown to protect against the induction of allergen-induced AHR by triggering increased production of both IL-10 and the Th1-derived cytokine, IFN-γ. Recent studies indicate that this protective effect is dependent on γδ T cells, possibly activated through antigen-independent mechanisms such as increases in TNF-α production by DCs and macrophages, after uptake of mycobacteria. γδ T cells may exert their immunoregulatory effects by acting directly on airway epithelial cells to inhibit the release of factors that, either directly or indirectly through stimulation of Th2-mediated inflammatory responses, result in AHR (Kanehiro et al. 2001; Rha et al. 2002).

Lipopolysaccharide/endotoxin, a major constituent of bacterial cells walls, also appears to downregulate Th2 responses by stimulating production of the immunosuppressive and anti-inflammatory cytokine IL-10. Studies in rodent models have shown that exposure to LPS either before or during allergen provocation can protect against the induction of Th2-mediated airway inflammatory responses and eosinophilia, but failed to protect against the development of AHR (Gerhold et al. 2002). Furthermore, once airway inflammation has been established, exposure to LPS exacerbates the inflammatory response (Tulic et al. 2000).

LPS also induces secretion of IL-10 by a number of cell types, including DCs, which are critical for priming T-cell responses to allergens. This has led to speculation that LPS may protect against the development of asthma by the induction of immunoregulatory mechanisms rather than, or in addition to, protecting against Th2 immunity. A number of pathogens appear to trigger IL-10 production. Epidemiological studies have identified a disassociation between helminth infection and allergic disease. The induction of IL-10 production by parasites was associated with reduced skin test reactivity to aeroallergens (van den Biggelaar et al. 2000). This has led to the hypothesis that the immune system may have evolved mechanisms, such as the production of IL-10, for limiting the extent of the inflammatory response to microbial pathogens. The decrease in exposure to parasites or infectious agents, which has occurred in the western world over the last few decades, may account for a reduction in inherent immunoregulatory mechanisms. This may also explain the increasing incidence of autoimmune diseases, which have paralleled the rise in incidents of allergic asthma. Notably, animal studies have demonstrated that IL-10 knock-out mice are highly susceptible to both Th1- and Th2-mediated inflammatory diseases (Hoffmann et al. 2000). Furthermore, mucosal tolerance, which is thought to depend on IL-10 production, cannot be readily induced in animals kept in germ-free conditions, suggesting a minimal requirement for nonpathogenic gut microflora (Sudo et al. 1997). Epidemiological studies have found a significant correlation between the use of antibiotics during the first year of life and the subsequent development of allergic diseases (Wickens et al. 1999). The frequent use of antibiotics may have resulted in a reduction in the gut microflora.

The potential importance of IL-10 in regulating the asthmatic phenotype was revealed in comparative studies, which showed a marked reduction in IL-10 protein levels in BAL fluid of patients with allergic asthma and in cultures of peripheral blood cells on stimulation with LPS, suggestive of an inherent defect in IL-10 production (Borish et al. 1996). Nevertheless, it is highly likely that, in addition to IL-10, a number of other factors, including TGF-β and the activity of $CD4^+CD25^+$ regulatory T cells, contribute to the regulation of immunopathological processes that are involved in bronchoconstriction and AHR. Furthermore IL-10, although exhibiting protective properties during the induction and effector phase of asthma, can also under certain circumstances contribute toward increased AHR.

Immunoregulatory and pathogenic roles of IL-10 in AHR

The role of IL-10 in the development of AHR remains disputed. Evidence for an association between elevated IgE levels and polymorphisms in the promoter region of the IL-10 gene (Hobbs et al. 1998) is backed by clinical studies that have revealed reduced levels of IL-10 transcripts and protein levels in BAL fluid obtained from patients with allergic asthma (Borish et al. 1996). Furthermore, successful standard immunotherapy to insect venom, as assessed by reductions in clinical symptoms on allergen exposure, correlated with an increase in IL-10 production by allergen-reactive T cells in the periphery (Akdis et al. 1998). Animal models have been used in an attempt to evaluate the role of IL-10 in the pathogenesis of asthma and AHR. These studies suggest that, although generally considered as a regulatory and anti-inflammatory cytokine, IL-10 can also contribute toward the pathophysiology of AHR in asthma. Zuany-

Amorim demonstrated that administration of IL-10 into the airways of mice at the time of antigen challenge, but not later, caused a marked reduction in IL-5 production and airway eosinophilia, suggesting that IL-10 may inhibit localized priming of Th2 responses (Zuany-Amorim et al. 1995; Yang et al. 2000). A role for endogenous IL-10 in regulating T-cell-mediated inflammatory responses was confirmed using IL-10 gene knock-out mice (Grunig et al. 1997). An independent study revealed that, in spite of developing pronounced airway inflammation associated with increased levels of the Th2 cytokines IL-5 and IL-13 in BAL, eosinophilia, and mucus production, IL-10-deficient mice failed to develop AHR. Transfer of the IL-10 gene before allergen challenge of the airways was sufficient to reconstitute AHR in sensitized mice, indicating that IL-10 is an important cofactor for induction of AHR (Makela et al. 2000; Justice et al. 2001). However, in the absence of prior sensitization and challenge of the airways with allergen, IL-10 alone is insufficient to induce AHR (Van Scott et al. 2000). In view of the various studies performed to date, it is likely that the role played by IL-10 in the induction of AHR is indirect and not unique. Studies have shown that AHR could be induced after respiratory syncytial virus (RSV) infection of IL-10-deficient mice exhibiting allergen-induced airway inflammation. Furthermore, reductions in airway eosinophilia following treatment of RSV-infected mice with anti-IL-5 neutralizing antibody significantly reduced AHR following allergen exposure, indicating a potential role for eosinophil-derived factors in AHR (Makela et al. 2002). Previous studies indicated that the Th2 cytokines, IL-5 and IL-13, contribute directly toward AHR, suggesting that factors released during airway inflammation are also required for induction of AHR (Foster et al. 1996; Garlisi et al. 1997; Grunig et al. 1998; Hogan et al. 1998; Wills-Karp et al. 1998). Recent studies have shown that eosinophils derived from patients with asthma express IL-13, and furthermore that IL-13. Furthermore, following stimulation with IL-5, IL-13 can be induced in eosophinols obtained from non-asthmatic controls. These data suggest that in an allergic Th2 cytokine-driven asthmatic response, eosinophils, by acting as a source of IL-13, may contribute indirectly towards the induction of AHR (Schmid-Grendelmeier et al. 2002). Most probably elevated levels of IL-13, arising as a result of IL-10-mediated suppression of Th1 cytokine responses, may be a compounding factor in the onset of AHR, because many of the factors known to contribute toward AHR, including mucus metaplasia, are IL-13 dependent.

Immunoregulatory role of IL-12

Allergic asthma and AHR is associated with skewed Th2 cytokine production. It has been proposed that the balance between IL-12-induced Th1 responses and levels of Th2 cytokines, notably IL-4 and IL-13 in the airways, or responsiveness to these cytokines could influence development of an allergic asthmatic phenotype. Interestingly, the genes encoding the Th2 cytokines (IL-4, IL-5, IL-9, and IL-13), as well as the p40 subunit of IL-12, are located within chromosome 5q (Marsh et al. 1994). Identification of rare polymorphisms in the promoter region of the IL-12 subunit genes (Pravica et al. 2000) and their association with disease severity (Morahan et al. 2002) has led to speculation that a failure to suppress aberrant Th2-mediated responses to common aeroallergens in genetically predisposed individuals results in the development of allergic diseases. IL-12, produced by antigen-presenting cells including DCs and macrophages after stimulation with microbial pathogens, is critical for the development of a Th1 phenotype (Trinchieri 1994). Signaling through the IL-12 $R\beta_2$ subunit is required for Th1 differentiation after STAT4 nuclear translocation and IFN-γ gene transcription. Notably, cells expressing a Th2 phenotype have lost IL-$12R\beta_2$ expression and therefore their ability to respond to IL-12 (Szabo et al. 1995).

There is increasing evidence from clinical studies that a deregulated IL-12 response may contribute toward the development of an asthmatic phenotype. Bronchial biopsy specimens taken from patients with allergic asthma were found to contain lower levels of IL-12 p40 mRNA than healthy controls (Naseer et al. 1997). The immunoregulatory cytokines TGF-β and IL-10 as well as a number of factors associated with the allergic inflammatory response, in particular IL-4, IL-13, and the inflammatory mediators PGE_2 and histamine, can down-regulate IL-12 production, thereby further amplifying the allergic response (Van der Pouw Kraan et al. 1995; Meyaard et al. 1996; Elenkov et al. 1998). An increase in IL-12 and decrease in IL-13 levels after steroid treatment were observed only in those patients who responded to therapy. Failure to respond to steroid treatment may be linked to reduced levels of IL-$12R\beta_2$ chain expression (Matsui et al. 1999; Wright et al. 1999).

Studies in murine models of allergic disease have demonstrated the importance of IL-12 in regulating pathogenic Th2 responses. IL-12 appears to play a critical role in protecting against the initial induction of allergic responses. Blockage of endogenous IL-12 in the unresponsive C3H/HeJ strain resulted in development of Th2-mediated responses on allergen exposure with elevated serum IgE levels, eosinophilic infiltration of the airways, and enhanced AHR (Keane-Myers et al. 1998). IL-12 knock-out mice showed enhanced levels of eosinophils in bone marrow and BAL following antigen challenge, compared with wild-type controls (Zhao et al. 2000). Administration of IL-12 during either sensitization or allergen challenge markedly reduced AHR (Kips et al. 1996; Sur et al. 1996; Schwarze et al. 1998). Suppression of Th2-mediated airway responses was asso-

ciated with a Th1 shift in cytokine responses. Nevertheless, studies in IFN-γR knock-out mice revealed that, although the initial inhibition of IgE production by IL-12 was IFN-γ dependent, suppression of airway eosinophilia and AHR was only partially dependent on IFN-γ, suggesting that other mechanisms are involved in mediating late phase inflammatory responses and AHR (Brusselle et al. 1997). A clinical study demonstrated that subcutaneous administration of recombinant IL-12 had no effect on the late phase airway hyperresponsiveness to allergen challenge, despite a significant reduction in eosinophil numbers and an improvement in the immediate acute hypersensitivity response (Bryan et al. 2000).

CONCLUSIONS

Asthma is a disease of the airways associated with pulmonary inflammation, eosinophilia, mucus hypersecretion, and increased AHR. Although both polygenic and multifactoral in origin, the recent rise in prevalence of asthma in the developed world has increased interest in the immunological mechanisms underlying the pathophysiology of disease. Asthma is associated with recruitment of activated $CD4^+$ Th2 cells producing IL-4, IL-5, IL-9, and IL-13. These cytokines exhibit considerable functional redundancy and only recently, through the use of animal models, has it been possible to establish their role in the asthmatic response. Whereas IL-4 is essential for the induction of Th2 responses, IL-13 appears to be essential for the late phase response associated with AHR. Through the induction of chemokines, IL-13 mediates the recruitment and activation of $CD4^+$ Th2 lymphocytes and eosinophils involved in airway inflammation. In addition, IL-13, through its direct effects on resident airway epithelial cells, fibroblasts, and smooth muscle cells, mediates mucus hypersecretion, tissue fibrosis, and AHR.

The correlation between the rise in incidence of asthma and reduced exposure to bacterial and parasitic infections, which has arisen as a result of improved living standards, has led to speculation that anti-inflammatory responses induced by these agents may protect against the development of aberrant Th2 immune responses to environmental allergens. Immunoregulatory mechanisms, which include IL-10 production by DCs, are also involved in mucosal tolerance induction on exposure of the airways to allergen.

DEFINING AUTOIMMUNITY AND AUTOIMMUNE DISEASE

Autoimmunity is defined as activation of an immune response against self-tissue (Ermann and Fathman 2001). A degree of autoimmunity, or self-reactivity, is a phenomenon that occurs even in healthy individuals. Alternatively, autoimmune disease is an 'attack', which may afflict patients with conditions that are debilitating, even life threatening. Autoimmune disease is marked by the presence of pathogenic antibodies and/or lymphocytes that target self-antigens and mediate tissue destruction. A multitude of factors influence one's susceptibility to autoimmune disease, including host genetics, environmental factors, and immune disregulation (Ermann and Fathman 2001) (Figure 1).

The subject of autoimmune disease encompasses a broad spectrum of illnesses of ambiguous etiology and pathogenesis. Despite the uncertainty underscoring any discussion of autoimmune disease, unambiguous evidence demonstrates that self-tolerance has been corrupted. The main function of the immune system is to protect self from nonself. For this purpose, it must operate by its ability to discriminate between what is self and what is not, a paradigm first described by Burnet in

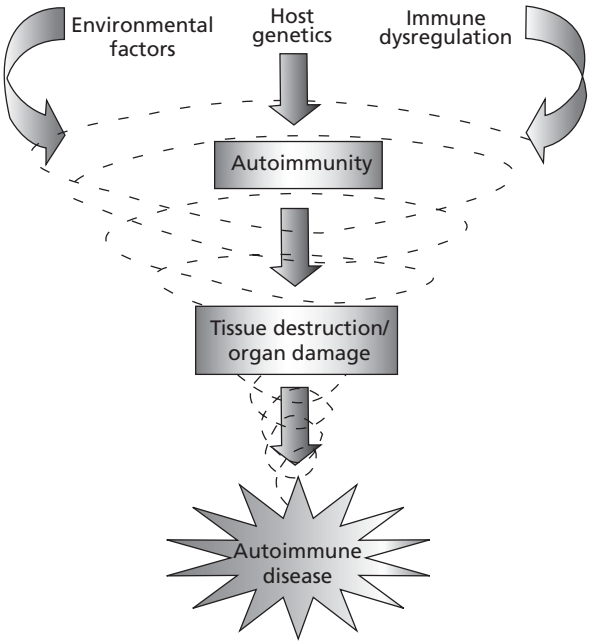

Figure 1 *Etiology of autoimmune disease: with several factors underlying its etiology, the development of an autoimmune response is a downward spiral, resulting in tissue destruction, organ damage, and autoimmune disease.*

1959. 'Survival requires both the ability to mount a destructive immune response against non-self and the inability to mount a destructive response against self' (Huston 1997). With a break in self-tolerance, the immune system proceeds to attack itself with the same vigor as it would to eliminate an infectious organism. Ultimately, the dangerous cascade of an autoimmune disease may compromise survival.

Autoimmune diseases affect approximately 5 percent of the global population (Jacobson et al. 1997). In the USA, roughly 14 million people are afflicted with various autoimmune diseases. Women are disproportionately affected, because they represent 75 percent of autoimmune disease patients. To date, over 80 distinct types of autoimmune diseases have been identified. Diseases may be categorized into one of two groups: organ-specific or systemic autoimmune disease (Table 1). In organ-specific autoimmune diseases, including Graves' disease (Weetman 2001) and type 1 diabetes (Wucherpfennig and Eisenbarth 2001), the targeted self-antigen is expressed only in the affected organ, whereas, in systemic autoimmune diseases, the self-antigen is expressed throughout the host eliciting tissue damage systemically. Systemic lupus erythematosus (SLE) and rheumatoid arthritis (RA) are two systemic autoimmune diseases with a high prevalence in the USA (Jacobson et al. 1997).

THE DISCOVERY AND REDISCOVERY OF AUTOIMMUNITY

The study of autoimmunity has a controversial, albeit intriguing, history (Silverstein 2001). In 1901, Paul Ehrlich, famed immunologist, adamantly denounced the existence of autoimmune disease or what he dubbed as *horror autotoxicus*. Ehrlich declared that it would be against the design of nature for an organism to jeopardize itself by producing pathogenic autoantibodies. Shortly thereafter, investigators Julius Donath and Karl Landsteiner published findings regarding the pathogenesis of paroxysmal cold hemoglobinuria (PKH). PKH is an unusual disease whereby patients develop acute intravascular red blood cell destruction and subsequent hemoglobinuria following exposure to the cold. In 1904, they proposed that this rare disease is autoimmune in origin, citing their demonstration of a pathogenic autoantibody that reacts with its target cell in the cold. Suffice it to say, Ehrlich and his colleagues disputed these findings and maintained their stance that autoimmune disease did not exist, thereby influencing generations of immunologists to come.

The concept of autoimmunity as a disease model reappeared in the 1950s. Ernest Witebsky published a report demonstrating the induction of autoimmunity in an animal model of chronic thyroiditis (Witebsky and Rose 1956). Indeed, Witebsky was an unlikely candidate to reintroduce the concept of autoimmunity, because he was a faithful disciple of Ehrlich and his campaign to refute autoimmunity. Despite the initial resistance of Ehrlich, Witebsky, and other investigators to acknowledge the existence of autoimmunity, today it is recognized as a major societal burden. Intensive investigative efforts are focused on uncovering the etiology, mechanisms, and treatments for many autoimmune diseases.

MECHANISMS OF TOLERANCE

The ability of the immune system to protect the body against challenge from innumerable exogenous pathogens is conferred in part by a diverse lymphocyte repertoire. In fact, the total diversity of the αβ T-cell receptor (TCR) and B-cell immunoglobulin (Ig) repertoires is estimated at 10^{18} and 10^{14}, respectively (Janeway et al. 2001). This diverse repertoire supports B- and T-cell recognition of a broad range of antigens. The tremendous degree of diversity is further enhanced by the 'plasticity' or cross-reactivity of the receptors (Mason 1998). This flexibility has been attributed to conformational changes in the TCR that occur during engagement of the major histocompatiblity complex (MHC) (Garcia et al. 1998). Given the capacity to recognize countless

Table 1 *Prevalence of autoimmune diseases: top ten autoimmune diseases in order of decreasing prevalence*

Disease	Prevalence (%)	Category	Target
Graves' disease	1.1	Organ specific	Thyroid
Rheumatoid arthritis	0.9	Systemic	Joints, lungs, heart, etc.
Hashimoto's thyroiditis	0.8	Organ specific	Thyroid
Vitiligo	0.4	Organ specific	Melanocytes
Type 1 diabetes	0.2	Organ specific	Pancreatic β cells
Pernicious anemia	0.15	Organ specific	Gastric mucosa
Multiple sclerosis	<0.1	Organ specific	Brain (spinal cord)
Glomerulonephritis	<0.1	Organ specific	Kidney
Systemic lupus	<0.1	Systemic	Skin, joints, kidney, brain, blood, lungs, etc.
Sjögren's syndrome	<0.1	Organ specific	Lacrimal and salivary glands

(Jacobson et al. 1997)

antigens, it is not surprising that lymphocytes may inadvertently recognize self-antigens and mount an autoimmune response.

Two criteria underlie the mechanisms by which the immune system protects the body against autoimmunity: self-recognition and self-tolerance. At the initiation of an immune response, self-recognition, or the ability to discriminate between what is self and what is nonself or foreign, is intrinsic to the goal of targeting only foreign antigens. As an immune response is maintained, self-tolerance, or the ability to silence self-reactivity, is an essential component for halting autoimmunity. One of the most effective mechanisms to ensure both self-recognition and self-tolerance is positive and negative selection during T-cell maturation. This occurs centrally in the thymus from the perinatal period until puberty. Later in development, other critical mechanisms of tolerance induction occur in the periphery, including the suppression or elimination of autoreactive lymphocytes.

Establishing self-tolerance in the central lymphoid organs

The first and most effective route for eliminating autoreactive lymphocytes occurs during central tolerance induction in the bone marrow and thymus. After the rearrangement and expression of Ig and TCR genes, B and T cells express antigen-specific receptors. These receptors may have specificity for either self or nonself antigens. Although T cells with high avidity for self-determinants are clonally deleted in the thymus on encounter of self-antigens in association with self-MHC, self-reactive B cells in the bone marrow may escape deletion and modify their Ig by receptor editing (Tiegs et al. 1993).

Central tolerance is an insufficient route for eliminating the entire autoreactive T- and B-lymphocyte population. An analysis of multiple sclerosis (MS) patients demonstrated that autoreactive T cells specific for myelin basic protein (MBP) escape deletion during thymic selection (Ota et al. 1990). Upon activation in the periphery, perhaps during a viral infection, these cells may initiate the destruction of the central nervous system. Self-reactive lymphocytes may escape deletion for several reasons. In the thymus, some self-antigens may not be expressed at sufficient levels to mediate deletion or, perhaps, some self-antigens are not present at all.

Maintaining self-tolerance in the periphery

In the periphery, autoreactive T cells are held in check by tolerance mechanisms that may be characterized as T-cell intrinsic or T-cell extrinsic mechanisms (Walker and Abbas 2002). T-cell intrinsic mechanisms act directly on the T cell, whereas T-cell extrinsic mechanisms involve the tolerogenic functions of additional cells.

T-CELL INTRINSIC MECHANISMS OF PERIPHERAL TOLERANCE

Intrinsic mechanisms include the following: ignorance, anergy, phenotypic skewing, and apoptosis (Walker and Abbas 2002).

T-cell ignorance

This is the process by which autoreactive T cells (or B cells) are unresponsive to antigen. The T cells may ignore the self-antigen because either it binds the TCR with low affinity or it is present at a low concentration (Janeway et al. 2001). Kurts et al. (1999) experimentally documented this state by transferring ovalbumin-specific lymphocytes to mice expressing low levels of pancreatic ovalbumin. The T cells remained ignorant of the ovalbumin antigen at low doses, but were responsive to the antigen at high doses. Interestingly, tissue-specific antigens, such as insulin in the pancreas, are expressed at high concentrations at specific sites. These antigens often have a higher association with autoreactivity (Janeway et al. 2001).

Some T cells remain ignorant because they are never exposed to inaccessible self-antigens, e.g. intraocular proteins are sequestered in the eye, an immunologically privileged site. Unless these proteins are released, autoreactive T cells specific for these proteins are never activated.

T-cell anergy

The state of anergy occurs when lymphocytes do not respond to antigen stimulation. In vivo, T-cell inactivation resulting from anergy induction is dependent on the recognition of the B7 molecule by CTLA-4 (Perez et al. 1997). In mice, the significance of anergy induction is demonstrated by CTLA-4 deficiency that results in severe lymphoproliferation and early death (Waterhouse et al. 1995). The association between CTLA-4 and autoimmune diseases is discussed.

Phenotypic skewing

The induction of tolerance via phenotypic skewing is dependent on which cytokine and chemokine profile is elicited after T-cell activation by a self-antigen. A self-antigen alone may only be able to induce a T-helper type 2 (Th2) response, which is associated with dampening autoimmunity. A self-antigen in association with additional adjuvants, such as the case with bacterial lipopolysaccharide (LPS), may induce a shift towards a T-helper type 1 (Th1) response. The proinflammatory Th1 response is associated with perpetuating an autoimmune response.

Apoptosis

Apoptosis via activation-induced cell death (AICD) is a mechanism for eliminating self-reactive B and T cells in the periphery. The process of apoptotic cell death promotes an anti-inflammatory environment via two routes: (1) inhibition of proinflammatory cytokines by monocytes and macrophages and (2) inducing the release of immunosuppressive cytokines, including IL-10 and transforming growth factor β (TGF-β) (Savill et al. 2002).

Self-reactive, immature B cells expressing surface IgM are eliminated by apoptosis (Janeway et al. 2001). In the case of self-reactive T cells, Walker and Abbas (2002) postulate that the repetitive engagement of TCR by ubiquitous self-antigens may induce the upregulation of the cell-death Fas ligand, thereby initiating AICD. The significance of Fas-mediated apoptosis as an immunoregulatory mechanism to eliminate autoreactive lymphocytes is demonstrated in humans with autoimmune lymphoproliferative syndrome (ALPS). These patients have deleterious defects in the Fas pathway that result in expanded lymphocyte populations and compromised peripheral self-tolerance (Fisher et al. 1995).

T-CELL EXTRINSIC MECHANISMS OF PERIPHERAL TOLERANCE

Extrinsic tolerance mechanisms evoke the functions of dendritic cells (DC) and regulatory T cells (Walker and Abbas 2002). Although it is apparent that both DCs and regulatory T cells play a role in determining whether an immune response is enhanced or suppressed, the precise mechanism of action of these cell types remains to be determined.

Dendritic cells

The DC is a powerful antigen-presenting cell (APC) located in the skin, blood, and lymphatic network (Steinman and Nussenzweig 2002). Immature DCs capture and process antigens, whereas mature DCs, in the presence of infection, present these antigens in association with MHC to T cells (Yewdell and Tscharke 2002) (Figure 2). Immature DCs are associated with T-cell tolerance, whereas mature ones are associated with T-cell activation. As DC maturation plays a crucial role in initiating and modulating the immune response, it is subject to regulation, e.g. the maturation and presentation of antigen by DCs is inhibited upon the uptake of dying, apoptotic cells in an effort to maintain tolerance and suppress autoimmunity (Savill et al. 2002). In addition, the maturation of DCs is inhibited by the anti-inflammatory cytokine, interleukin (IL)-10 (Haase et al. 2002).

Dendritic cells also play a role in providing signals to distinguish between an appropriate antigen, as in the case of a pathogen, or an inappropriate antigen, such as a self-antigen. In 1992, Janeway postulated that DCs have pattern-recognition receptors that are specific for motifs associated with microorganisms. The engagement of these receptors triggers an immune response. This

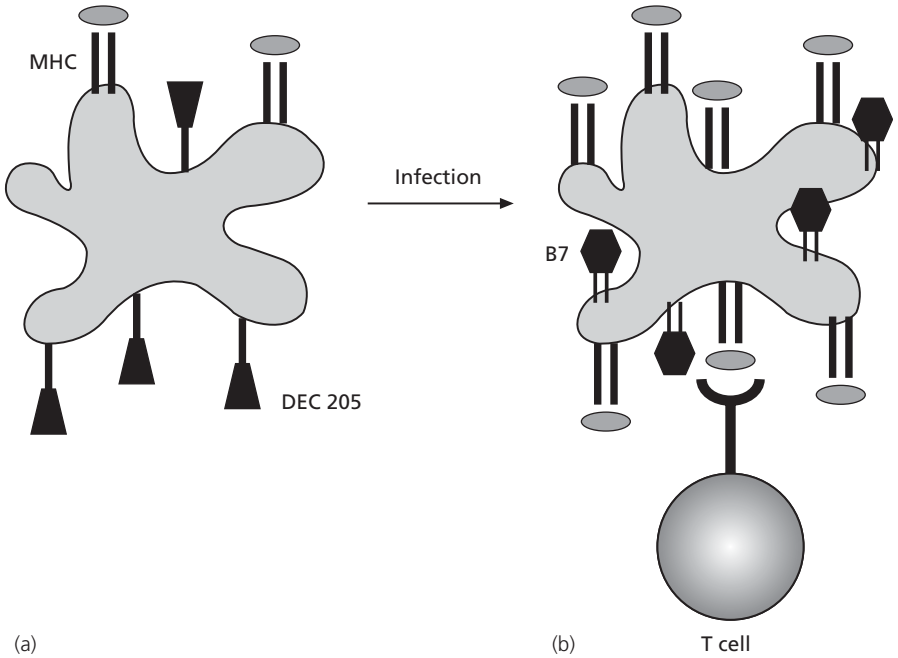

Figure 2 (a) *Immature and* **(b)** *mature dendritic cell phenotypes: immature dendritic cells are located in the surface epithelia and solid organs. They express low levels of major histocompatiblity complex (MHC) molecules, as well as the DEC 205 molecule, an antigen-phagocytosing receptor. During infection, immature dendritic cells migrate to lymphoid tissue. These mature dendritic cells increase expression of MHC and B7, a co-stimulatory molecule (Janeway et al. 2001).*

theory was substantiated in 1997 with the identification of Toll-like receptors (TLR) (Medzhitov et al. 1997). TLRs, on the recognition of molecular patterns present on microorganisms, induce an immune response that includes the expression of co-stimulatory molecules and the release of cytokines (Gordon 2002).

Regulatory T cells

Regulatory or suppressor T cells that co-express CD4 and CD25 (the interleukin IL-2 receptor α chain) represent less than 5 percent of the T cells in the blood. These 'sentinel' T cells have the capacity to monitor immune responses by suppressing both $CD4^+$ and $CD8^+$ T cells (Steinman and Nussenzweig 2002). The mechanism of suppression has not yet been elucidated, although it is associated with decreased levels of IL-2 transcription (Thornton and Shevach 1998). The critical role of regulatory T cells in tolerance is demonstrated in a mouse model where a reduced level of regulatory T cells is associated with autoimmune disease (Asano et al. 1996).

Regulatory cells are also subject to immunoregulation. IL-10, a suppressor cytokine, may trigger the generation of regulatory cells. In addition, the presence of immature DCs may generate regulatory T cells (Shevach 2002). DCs mature in the presence of TLR signaling; the absence of mature DCs may be a marker for the absence of an invading pathogen, favoring the suppression of a potential autoimmune response.

GENETICS AS A FACTOR IN AUTOIMMUNE DISEASE SUSCEPTIBILITY

A role for genetic predisposition in autoimmune disease development was suspected, given the propensity for familial aggregation of certain autoimmune diseases. The association was positively identified by a study of the disease concordance rates in monozygotic twins. The disease concordance rates for certain autoimmune diseases, such as type 1 diabetes and SLE, were quite high, 50 and 57 percent, respectively (Jarvinen et al. 1992; Kumar et al. 1993; Redondo et al. 1999). By comparison, the incidence for diabetes and SLE in the general population is significantly less, 0.4 and 0.2 percent, respectively, suggesting an underlying genetic component to disease development.

Today, at the forefront of the search for autoimmune disease genes, there are powerful tools, including linkage analysis, animal models, and gene chip microarrays (Wanstrat and Wakeland 2001). Despite these advantages, the search for genes affecting autoimmune disease is complicated by several factors, including genetic heterogeneity. Genetic heterogeneity, or the various combinations of genes that contribute to a certain phenotype, underlies the genetic predisposition to most autoimmune diseases (Wanstrat and Wakeland 2001). A clear characterization of the role of genetic predisposition in autoimmune disease development is further obscured by epistatic interactions between 'susceptibility genes' and 'resistance genes' (Ermann and Fathman 2001). Fortunately, completion of the Human and Murine Genome Projects offer valuable maps of the mammalian genome that will probably facilitate groundbreaking discoveries in the search for autoimmune disease genes.

The effects of MHC genes on autoimmune disease development

The most intensely studied genes associated with autoimmune disease development are the alleles of the MHC. These genes encode cell-surface molecules on APCs that bind peptides for presentation to antigen-specific T lymphocytes. Some hypothesize that the association between MHC and autoimmune disease susceptibility originates during T-cell development. During this period, the signals resulting from the TCR and MHC molecule–peptide complexes shape the thymic T-cell repertoire and may potentiate the escape of autoreactive T cells. Particular class II MHC molecules may select for autoreactive T cells by increasing positive selection or decreasing negative selection (Marrack et al. 2001), e.g. the MHC II molecule, $I\text{-}A^{g7}$, in the nonobese diabetic (NOD) mouse model, binds peptides very poorly (Carrasco-Marin et al. 1996). If self-peptides are inadequately presented by $I\text{-}A^{g7}$ during selection, self-reactive T cells will not be eliminated. Others speculate that the linkage between MHC and autoimmunity is a simple scenario whereby disease susceptibility is determined by the varying degree to which different MHC alleles present self-peptides to autoreactive T cells (Janeway et al. 2001). In the periphery, certain disease-associated MHC II molecules predispose to autoimmunity by presenting self-peptides to autoreactive $CD4^+$ T cells.

The MHC and autoimmune disease linkages are identified by comparing the frequency of certain alleles in patients to the frequency of those alleles in the normal population (Janeway et al. 2001). One of the earliest links between autoimmunity and MHC was noted in the 1970s (Feldmann 2001). HLA-DR (human leukocyte antigen DR) allele subtypes were associated with RA via a 'shared epitope', a six amino acid sequence occurring in the peptide-binding groove of the DR alleles of 70–80 percent of RA patients. Currently, the HLA-DR alleles, HLA-DRB1*0401 and -*0404, are recognized as the most significant contributors to genetic susceptibility to RA (Nepom 1998).

Multiple sclerosis is also associated with particular alleles of HLA-DR, specifically HLA-DR2, as well as alleles of HLA-DQ. However, a comprehensive linkage

Table 2 *Examples of some MHC/autoimmune disease associations*

Disease	Association	
	Class I MHC	Class II MHC
Reactive arthritis	HLA-B27	
Ankylosing spondylitis	HLA-B27	
Multiple sclerosis		HLA-DR2
Treatment-resistant Lyme arthritis		HLA-DR4, HLA-DR1
Rheumatoid arthritis		HLA-DR1, HLA-DR4
Type 1 diabetes		HLA-DQ8, HLA-DQ2

(Wucherpfennig, 2001)

analysis determined that disease development was probably the result of multiple environmental and genetic factors, as opposed to a single disease gene (Haines et al. 1996).

The HLA-DR and HLA-DQ alleles are also strongly associated with type 1 diabetes (Wucherpfennig and Eisenbarth 2001). Interestingly, the complexity arising from the interaction between 'disease-causing genes' and 'disease-modifying genes' is evident in a transgenic mouse model of type 1 diabetes. Mice transgenic for HLA-DQ8 develop spontaneous disease, but the frequency of disease is lower when the mice co-express HLA-DR4 and HLA-DQ8, suggesting a protective role for HLA-DR4 allele (Wucherpfennig and Eisenbarth 2001). In humans, the HLA-DR2–DQ6 haplotype, representing a linkage disequilibrium, is associated with dominant protection from type 1 diabetes (Nepom and Erlich 1991).

The vast majority of MHC and autoimmune disease associations are linked to class II molecules (Table 2), although there are exceptions. Ankylosing spondylitis and reactive arthritis are two examples; both diseases are strongly associated with the MHC I molecule, HLA-B27 (Levitin et al. 1976; Pasternack and Tiilikainen 1977).

The effects of non-MHC genes on autoimmune disease development

Genetic mapping studies have identified individual genes on various chromosomes associated with susceptibility towards certain autoimmune diseases. These non-MHC genes are involved in regulating the recognition, presentation, and concentration of autoantigens (Marrack et al. 2001). A polymorphism in the gene that encodes the CTLA-4 is linked to the development of type 1 diabetes, celiac disease, Graves' disease, and autoimmune hypothyroidism (Nistico et al. 1996; Djilali-Saiah et al. 1998). CTLA-4 is a surface T-cell molecule that negatively controls T-cell activation (Linsley et al. 1992). Another polymorphism in the gene encoding IL-2 is associated with NOD mice and experimental autoimmune encephalomyelitis (EAE) animal models (Encinas et al. 1999). IL-2 stimulates the proliferation of T lymphocytes *and* keeps lymphoid growth in check; this example underscores the significance of IL-2 in maintaining peripheral tolerance. A deficiency of C1q in certain strains of mice, as well as in humans, results in a lupus-like disease characterized by autoantibodies to double-stranded DNA or nuclear components (Slingsby et al. 1996; Botto et al. 1998). C1q, a component of the classic complement pathway, aids in the clearance of apoptotic cellular debris including potential nuclear autoantigens. Two mutations that encode transcription factors of unknown function have been implicated in type 1 diabetes, one on chromosome 21 and another on the X chromosome. The former, an autosomal recessive mutation, results in autoimmune polyendocrine syndrome type 1 (APS-1) (Nagamine et al. 1997), and the latter causes X-linked autoimmunity-allergic disregulation syndrome (XLAAD) (Chatila et al. 2000). Mice deficient in IL-10 develop chronic enterocolitis, a disease that is pathologically similar to inflammatory bowel disease (IBD) in humans (Kuhn et al. 1993). Clearly, many non-MHC genetic abnormalities have been associated with autoimmunity.

ENVIRONMENTAL FACTORS AND AUTOIMMUNE DISEASE

An individual's predisposition towards acquiring an autoimmune disease is influenced not only by genetic susceptibility, but also by the environment. In humans, incomplete autoimmune disease concordance rates in monozygotic twins suggest an underlying environmental component to autoimmune disease development. In identical twin pairs, less than 50 percent of the siblings of affected twins will acquire an autoimmune disease (Ermann and Fathman 2001). An intriguing epidemiological study of the incidence of MS in a migrant population revealed that migrants acquired the MS risk of the region to which they relocated (Weinshenker 1996). In animals, inbred strains susceptible to the spontaneous development of SLE and diabetes display incomplete disease penetrance (Wanstrat and Wakeland 2001). In NOD mice, the incidence of diabetes drops dramatically with bacterial infection (Todd 1991).

The association between infectious agents and autoimmune disease has been the subject of intense investigation over the course of the last two decades. Even since its earliest description, autoimmune disease has been linked with infection. In the aforementioned research on PKH, the collaborators Donath and Landsteiner were struck by the correlation between PKH and a pre-existing syphilis infection (Silverstein 2001). To date, contemporary researchers have added considerably to the number of autoimmune diseases linked with pathogens (Table 3). The classic examples include: β-hemolytic streptococci and rheumatic fever (Benoist and Mathis 1998); *Trypanosoma cruzi* and Chagas' disease

Table 3 *Pathogens and autoimmunity: some common examples of autoimmune diseases linked with pathogens*

Disease	Pathogen	Host self-antigen
Rheumatic fever	Group A streptococci	Cardiac myosin
Guillain–Barré syndrome	*Campylobacter jejuni*	Peripheral nerve ganglioside proteins
Treatment-resistant Lyme arthritis	*Borrelia burgdorferi*	LFA-1
Myocarditis	Group B Coxsackie virus	Cardiac antigens
Chagas' disease	*Trypanosoma cruzi*	Cardiac myosin heavy chain
Herpetic stromal keratitis	Herpes simplex virus	Cornal antigen and IgG2a
Type 1 diabetes	Group B Coxsackie virus	Glutamate decarboxylase
Myasthenia gravis	Herpes simplex virus	Acetylcholine receptor
Multiple sclerosis	Epstein Barr virus	Myelin basic protein

Benoist and Mathis (2001), Regner and Lambert (2001), Marrack et al. (2001).

(Khoury and Fields 1980); and *Borrelia burgdorferi* and Lyme arthritis (Gross et al. 1998). Animal models in which microbial infection directly triggers certain autoimmune diseases further support this link between infection and autoimmunity. In one such model, particular strains of mice develop an autoimmune response against a corneal antigen after ocular infection with herpes simplex virus 1 (Panoutsakopoulou et al. 2001). The mice develop herpetic stromal keratitis (HSK), a leading cause of blindness in humans (Streilein 1997).

Despite the pathogen and autoimmune disease correlations in both humans and mice, the exact mechanisms whereby an infection leads to autoimmune disease have not yet been resolved. In fact, it remains unclear as to whether the pathogen directly or indirectly contributes to autoimmune disease development. Possibly, cross-reactive immune responses against the pathogen and self-molecules closely resembling the pathogen produce disease. Or, perhaps, the inflammation provoked by the pathogen at the site of infection causes a disregulated immune response that disturbs self-tolerance. The etiology of an autoimmune disease triggered by infection may be multifactorial, implicating several mechanisms in pathogenesis that may be relevant at different disease stages (Wucherpfennig 2001).

Mechanisms for pathogen-induced autoimmunity

Several mechanisms have been proposed to account for the post-infectious activation of the immune response against self-targets (Wucherpfennig 2001). Mechanisms may be categorized into two groups: antigen-specific and antigen nonspecific. In the first group, the pathogen directly induces autoimmunity through an antigen-specific response involving a microbial product; molecular mimicry is a well-characterized example. In molecular mimicry, the immune response to a microbial antigen cross-reacts with a host antigen. In the second group, the response is antigen nonspecific; autoimmunity is a product of the pathogen-induced inflammatory environment, e.g. inflammation might prompt the expansion of previously activated T cells, a mechanism known as bystander activation (Wucherpfennig 2001).

ANTIGEN-SPECIFIC MECHANISMS FOR PATHOGEN-INDUCED AUTOIMMUNITY

Molecular mimicry

The theory of molecular mimicry argues that a viral or bacterial pathogen expresses an antigenic determinant on one of its proteins that is sufficiently similar in sequence or structure to a self-peptide (Fujinami and Oldstone 1985). During an infection, the microbial determinant, a linear sequence of 8–15 amino acids, may be presented in the context of a particular MHC molecule to the TCR of an autoreactive T cell. As a result, naïve autoreactive T cells are activated and expanded.

An animal model of EAE provided early evidence for molecular mimicry. Rabbits were immunized with a hepatitis B virus polymerase peptide which shared a six amino acid sequence similarity with the encephalitogenic region of rabbit MBP. After immunization with the peptide, T-cell reactivity to MBP could be demonstrated. Some of the animals also developed EAE as determined by histology (Fujinami and Oldstone 1985).

Autoimmune disease that is MHC I dependent was demonstrated in a mouse model of IBD. Intestinal inflammation was induced by transferring $CD8^+$ T cells, which recognize both mycobacterial and murine heat shock proteins (hsp) in TCR $\beta^{-/-}$ mice. The T-cell infiltrates into the small intestine and the liver resulted in lesions. The results could be reproduced in germ-free mice, implicating host hsp as a target for the $CD8^+$ T cells (Steinhoff et al. 1999).

A highly cited case for the role of molecular mimicry as a mechanism of autoimmune disease is in the pathogenesis of treatment-resistant Lyme arthritis (TRLA). Lyme disease is a multisystem illness caused by the tick-borne spirochete *Borrelia burgdorferi* (Steere et al. 1983). The Lyme disease pathogen expresses numerous antigens, including outer surface protein A (OspA) both on its surface and in its periplasmic space (Barbour and Hayes 1986). The clinical course of the disease begins

within days of the blood meal of the *Ixodes scapularis* tick. The characteristic rash, erythema migrans, occurs initially and is followed by cardiac, neurological, and musculoskeletal impairments, including joint inflammation (Steere 1989). A course of antibiotics typically resolves the illness. However, the arthritis never resolves in approximately 10 percent of patients despite extensive antibiotic therapy (Steere et al. 1984). These TRLA patients, who have no detectable spirochetal DNA in joint fluid or synovial tissue, are often HLA-DRB1*0401$^+$ and HLA-DRB1*0101$^+$, the same alleles associated with RA. Furthermore, during arthritic episodes, spiking titers of anti-OspA IgG are detectable in the patient serum (Kalish et al. 1993). These immune responses correlate with the severity and duration of the arthritis. Collectively, this evidence supports the hypothesis that TRLA is an autoimmune disease (Gross et al. 1998).

With molecular mimicry implicated as a mechanism for TRLA, the identification of the immunodominant epitope of OspA, as well as the search for a potential autoantigen, followed suit (Gross et al. 1998). Using an algorithm developed for the identification of peptides binding to HLA-DRB1*0401 (Hammer et al. 1994), $OspA_{165–173}$ was calculated to have the highest score for possible association with this class II molecule. To confirm that this was indeed the immunodominant epitope, HLA-DRB1*0401 transgenic mice were immunized with OspA and their immune T cells were tested in vitro for reactivity with an overlapping OspA peptide library. $OspA_{165–173}$ elicited the strongest recall response in these cells, a result that was confirmed by the response pattern of human T cells isolated from the synovial fluid of DRB1*0401$^+$ TRLA patients. A Genbank Database search for a human autoantigen with a similar amino acid sequence as seen in $OspA_{165–173}$ led to the identification of a stretch of amino acids from 332 to 340 in human leukocyte function antigen-1α (LFA-1α). T cells from the synovial fluid of TRLA patients were also responsive to human LFA-1α (Gross et al. 1998). According to the algorithm of Hammer et al. (1994), $LFA\text{-}1\alpha_{332–340}$ was predicted to be effectively bound by HLA-DRB1*0401.

With the identification of the candidate autoantigen, human LFA-1α, a model for autoimmunity as a mechanism for TRLA may be proposed. Following infection with *Borrelia burgdorferi*, the spirochete disseminates systemically to many locations, including the joint. After a period of varying duration, perhaps several months, the inflammatory immune response begins in the joint. The nine-residue peptide $OspA_{165–173}$ is presented in the context of HLA-DRB1*0401, resulting in activation and expansion of $OspA_{165–173}$-specific T cells and an inflammatory Th1 response, characterized by secretion of interferon γ (IFN-γ). The inflammatory milieu in the joint results in the upregulation of MHC II on APCs, as well as the upregulation of LFA-1α on leukocytes and synoviocytes. Despite the eradication of the spirochete by antibiotic treatment, the $OspA_{165–173}$-specific Th1 cells in the joint continue to be activated via cross-reaction with the self-peptide $LFA\text{-}1\alpha_{332–340}$, thus propagating the joint arthritis (Figure 3).

Superantigen activation

Viral or bacterial superantigens activate T cells expressing particular Vβ genes segments. Superantigens have

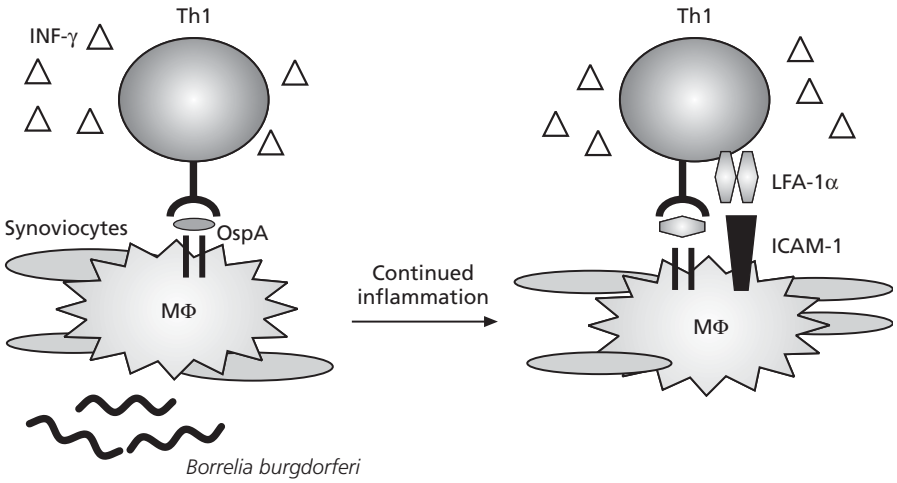

Figure 3 *Model for induction of autoimmunity in treatment-resistant Lyme arthritis (TRLA). Following infection with* Borrelia burgdorferi*, the spirochete disseminates systemically to many locations, including the joint. Macrophages (Mϕs) and dendritic cells present the outer surface protein* $OspA_{165–173}$ *to T cells. These activated T cells secrete interferon γ (INF-γ). The inflammatory milieu in the joint results in the upregulation of MHC II on antigen-presenting cells (APCs), as well as the upregulation of human leukocyte function antigen-1α (LFA-1α) on leukocytes and synoviocytes. Despite the eradication of the spirochete by antibiotic treatment, the cross-reactive T cells in the joint continue to be activated via the presentation of self-peptides derived from LFA-1α, propagating the joint arthritis. ICAM, intercellular adhesion molecule.*

the capacity to cause aberrant activation of large numbers of T cells, regardless of their peptide specificity. A subset of these superantigen T cells may be specific for a self-antigen and, thus, could mount an autoimmune response (Wucherpfennig 2001).

Superantigens may also exacerbate an autoimmune process or induce a relapse. In EAE, a murine model of MS, episodes of relapsing paralysis can be induced in PL/J mice with the bacterial superantigen staphylococcal enterotoxin B (SEB). In these mice, EAE is elicited by immunization with the amino-terminal peptide of MBP, Ac_{1-11}. Following an initial paralysis and clinical remission, administration of SEB can induce another episode of paralysis in these mice. The autoreactive T cells specific for the Ac_{1-11} epitope express Vβ8 and are reactivated by the SEB superantigen (Brocke et al. 1993).

ANTIGEN-NONSPECIFIC MECHANISMS FOR PATHOGEN-INDUCED AUTOIMMUNITY

Bystander activation

The inflammatory milieu resulting from a microbial infection may result in the expansion of autoreactive T cells in the absence of antigenic specificity. Activated T cells have a lower threshold for activation than resting T cells and, thus, may target self-antigens (Benoist and Mathis 1998). Microbial products, including LPS, can be potent adjuvants activating the innate immune response and eliciting an increase in proinflammatory cytokines. In this inflammatory environment, APCs enhance antigen processing, increase cell surface MHC II expression and upregulate co-stimulatory molecules such as B7-2 (Vella et al. 1997). Adjuvants may also sustain the antigen-specific T-cell population by inhibiting the AICD death of antigen-specific T cells (Kearney et al. 1994; Vella et al. 1997).

Another possible effect elicited by an inflammatory environment is a shift towards a Th1 T-cell population (Marrack et al. 2001). $CD4^+$ helper T cells differentiate into either Th1 or Th2 cells (Figure 4). Typically, microbial infections are associated with a Th-cell commitment to a Th1 cell (Yazdanbakhsh et al. 2002). This subset of cells is associated with the proinflammatory cytokine, INF-γ, and cell-mediated immunity. Th1 cells are also associated with many autoimmune diseases, including RA, Crohn's disease, type 1 diabetes, and MS. Comparatively, Th2 cells produce IL-4 and IL-5 and are associated with allergic and anti-helminth responses. After a microbial infection, the T-cell population may shift towards the Th1 subset, thereby priming an individual for an autoimmune disease. This theory remains hotly contested for a

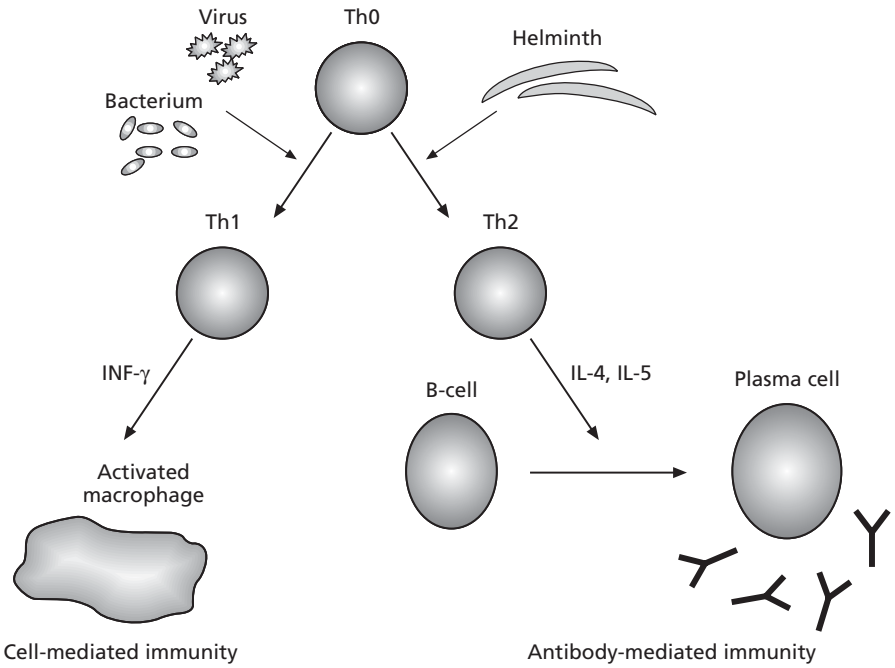

Figure 4 *T-helper 1 or 2 (Th1/Th2) cell phenotypes. $CD4^+$ Th cells differentiate into either Th1 cells or Th2 cells. The commitment to a Th1 or a Th2 cell fate is largely determined by transcriptional mechanisms induced by the interleukins IL-12 and IL-4, respectively (Murphy and Reiner 2002). In Th1 cell development, the T-box transcription factor T-bet is responsive to IL-12 and responsible for inducing the production of interferon α (INF-γ). During the commitment of Th cells to Th2 cells, IL-4 promotes the increased expression of the zinc finger transcription factor GATA3 which, in turn, enables the remodeling of the IL-4 locus. Typically, microbial and viral infections are associated with $CD4^+$ T-helper cell differentiation into Th1 cells (Lucey et al. 1996). This subset of cells is associated with activated macrophages secreting the proinflammatory cytokine, INF-γ, as well as cell-mediated immunity. Alternatively, Th2 cells produce IL-4 and IL-5 and are associated with allergic and anti-helminth responses. Th2 cells are associated with antibody-mediated immunity driven by plasma cells. (Adapted from Murphy and Reiner 2002 and Janeway et al. 2001.)*

variety of reasons, including the argument that cytokines have the dual capacity both to heighten and to constrain autoimmune responses. Furthermore, two common autoimmune diseases, ulcerative colitis and SLE, are associated with Th2 responses (O'Shea et al. 2002).

Epitope spreading

During chronic autoimmune disease, the T-cell response may acquire additional epitope specificities, shifting from a dominant epitope to subdominant epitopes on the self or foreign protein (Lehmann et al. 1992). 'Intramolecular spreading' refers to new epitopes on the same protein and 'intermolecular spreading' refers to epitopes on other proteins, perhaps other antigens in the same tissue (Vanderlugt and Miller 2002).

The earliest demonstration of this diversification of the T-cell response was shown in the murine model of EAE (Lehmann et al. 1992). After immunization with either whole MBP or only the N-terminal peptide of MBP ($Ac_{1–11}$), the T-cell response undergoes intramolecular epitope spreading, shifting reactivity from the original immunodominant peptide to different epitopes of the MBP protein. Evidence of intermolecular epitope spreading is depicted in a murine model of a chronic demyelinating disease mediated by $CD4^+$ T cells. Following infection with Theiler's picornavirus, mice develop a chronic progressive course of encephalomyelitis that resembles MS. The course of the disease appears biphasic. At the onset of clinical symptoms, T-cell responses to the virus are detected. Then, later in the course of the disease, responses to central nervous system antigens are seen, including determinants on the encephalitogenic proteolipid protein (PLP), MBP, and myelin oligodendrocyte glycoprotein (MOG).

Nonmicrobial environmental factors and autoimmunity

The evidence supporting a role for nonmicrobial environmental factors in the development of autoimmune disease is often based on epidemiological studies. Excessive intake of dietary iodide, a component of thyroid hormone, is a risk factor for autoimmune thyroid disease (Bagchi et al. 1985). Other studies correlate stressful life events with the development of Graves' disease (Matos-Santos et al. 2001). A recent study demonstrates that women who breast-feed have a decreased risk of developing SLE, a trend that is correlated with the number of babies breast-fed and the duration of breast-feeding (Cooper et al. 2002). Some literature cites occupational exposure to silica dust as a risk factor for the development of RA, lupus, scleroderma, and glomerulonephritis (Parks et al. 2002). In most cases, further studies are necessary to substantiate a role for nonmicrobial environmental factors in autoimmunity. However, in the case of sympathetic ophthalmia, there is unequivocal proof that trauma to one eye leads to an autoimmune-mediated attack of the other (Jakobiec et al. 1984). The eye is a well-defined immunoprivileged site, complete with T-cell infiltration barriers, and immunosuppressive cytokines, including TGF-β. When injury at this isolated site occurs, previously sequestered self-antigens are available for immunoreactivity.

THE EFFECTS OF IMMUNE DISREGULATION ON AUTOIMMUNE DISEASE DEVELOPMENT

Many of the immune regulation abnormalities identified in autoimmune disease are inextricably linked to genetic mutations, e.g. severe impairment of the AICD pathway results from mutations in the death receptor Fas (CD95) or Fas ligand (FasL or CD178). This pathway plays a critical role in maintaining peripheral tolerance via elimination of autoreactive cells. The absence of Fas or FasL in either *lpr* or *gld* mice, respectively, results in a severe autoimmune phenotype, an SLE-like disorder, marked by lymphadenopathy, autoantibody production, and nephritis (O'Shea et al. 2002). In humans, mutations in Fas result in ALPS. These patients present with lymphadenopathy, hepatosplenomegaly, and hypersplenism (Straus et al. 1999).

Other aberrant immunoregulatory mechanisms have not yet been linked to a single genetic defect, e.g. the T-cell response in active RA patients is dampened, perhaps as a result of aberrant calcium signaling and abnormal ξ chain expression by the TCR. These abnormalities may be a result of the overexpression of tumor necrosis factor α (TNF-α) in RA synovial tissue. These same abnormalities can be reproduced in vitro by chronic stimulation of T cells with TNF-α (Feldmann 2001).

Systemic lupus erythematosus may be the archetypal disease of immune disregulation. SLE, a systemic autoimmune disease, is defined by the production of autoantibodies. The disease has an enormous range of clinical manifestations that may involve the skin, joints, kidneys, and heart. SLE is associated with various abnormalities in lymphocytes at the cellular and molecular level that include antigen-receptor signaling events and cytokine production. In humans, abnormal, hyperreactive B-cell responses have been characterized. They include an increased expression of the CD40 ligand and a co-stimulatory molecule, as well as an increased production of the B-cell-stimulatory cytokines, IL-6 and IL-10 (Lipsky 2001). Altered T-cell signaling may result from the abnormal expression of the TCR ξ chain as well as decreased levels of p65-Rel A protein (Tsokos et al. 2000). The nuclear translocation of the p65-Rel A protein is associated with the activity of the transcription factor, nuclear factor-κB (NF-κB), which in turn is responsible for the activation of IL-2.

MECHANISMS OF TISSUE DESTRUCTION AND ORGAN DAMAGE IN AUTOIMMUNE DISEASES

The 'initiation phase' of an autoimmune disease is mediated by several factors: genetic predisposition, environmental influence, and immune disregulation (Ermann and Fathman 2001). Over time, a chronic autoimmune response invariably results in an 'effector phase' of the disease. During the effector phase, tissues and/or organs sustain damage imparted by destructive cells and cellular products. The effector phase of certain autoimmune diseases may be the product of both immune and nonimmune mechanisms (Ermann and Fathman 2001).

Demyelination and axonal loss in MS

Multiple sclerosis occurs in early adulthood and is the most common demyelinating disease in adults. The disease is characterized by relapsing and remitting episodes of neurological impairment. MS appears to be an autoimmune response targeting various proteins of the myelin sheath, including MBP, MOG, PLP, and αβ crystallin. Lymphocytes are initially activated by a microbial infection or a self-antigen, and then they are essentially 'pulled through' the blood–brain barrier by integrin and adhesion molecule interactions. After the degradation of the extracellular matrix by matrix metalloproteases (MMP), lymphocytes can access the white matter of the central nervous system, resulting in autoantibody production to myelin proteins by B cells and lymphotoxin-α (LT-α) and TNF-α cytokine secretion by T cells. These responses prompt the release of the free radical nitric oxide (NO) and the T-cell stimulator osteopontin (OPN) by macrophages, microglial cells, and astrocytes. The end result of this effector phase cascade is multifocal demyelination and axonal loss in the spinal cord, ultimately resulting in paralysis (Steinman 2001).

Immune complex deposition in SLE

Systemic lupus erythematosus is a systemic autoimmune disease that frequently strikes women during their reproductive years. In humans, this disease has an enormous range of clinical presentations which may include skin lesions, arthritis, serositis, nephritis, and hematological disorders. In fact, renal involvement is the most life-threatening complication of SLE. The immediate precursor to renal tissue destruction and kidney damage in SLE is the IgG autoantibodies to double-stranded DNA. Serum titers of these antibodies correlate with glomerulonephritis in humans and mice (Pearson and Lightfoot 1981). Other autoantibodies are also associated with the tissue destruction found in SLE, including anticardiolipin antibodies and thrombosis, as well as anti-Ro antibodies and congenital heart block (Lipsky 2001). Autoantibodies are the direct mediators of tissue injury in SLE. After the deposition of antigen–antibody immune complexes and the fixation of complement, tissue damage occurs in the manner of a type III hypersensitivity reaction.

Cartilage destruction and bone loss in RA

Another autoimmune disease, RA, afflicts about 1 in 100 people with chronic inflammation of the synovial joints. This chronic immune response ultimately destroys cartilage and bone, rendering the affected joints immobile. Although activated T cells specific for a joint antigen appear to be critical in the initiation of the disease process; cartilage and bone loss are also the products of nonimmune mediators. Enzymes play a critical role in cartilage destruction. Cartilage, an intricate matrix of type II collagen and aggrecan, is degraded by the activity of MMPs, as well as two aggrecanases or ADAMTS (a disintegrin or metalloproteinase with thrombospondin type I motif) (Feldmann 2001). Bone lesions are the product of the destructive osteoclast cell. Inflammation favors bone loss because osteoclastic precursors are induced to differentiate into osteoclasts by proinflammatory cytokines TNF-α and IL-1.

Thyroid-associated ophthalmopathy in autoimmune thyroid disease

Thyroid-associated ophthalmopathy (TAO) is a serious complication of autoimmune thyroid disease. The pathogenesis of TAO includes the deposit of excess connective tissue and fat in the orbital cavity, as well as edema. The clinical outcome is exophthalmos, corneal damage, and, on a rare occasion, loss of sight. The effector phase of TAO begins when the inflammatory cell infiltrate penetrates the extraocular muscles. These T cells mount a response against an orbital autoantigen that is similar enough to a thyroid autoantigen, inciting a cross-reaction. With the release of cytokines, including IL-1, TNF, and INF-γ, and the concomitant activation of fibroblasts, two mediators of edema are released by the fibroblasts: hydrophilic glycosaminoglycan hyaluronate and chondroitin sulfate (Weetman 2001). Interestingly, a subset of these orbital fibroblasts may differentiate into fat cells, explaining the excess orbital fat in TAO. Although the pathology of TAO is unraveling, the identity of the cross-reactive autoantigen remains at large.

EXPERIMENTAL ANIMAL MODELS OF AUTOIMMUNITY

The use of animal models has played a pivotal role in furthering our understanding of autoimmunity. Animal

models are implemented to investigate the etiology, pathogenesis, and therapeutic strategies associated with many of the 80 autoimmune diseases that collectively affect roughly 5 percent of the world's population. An animal model offers a wealth of information, far exceeding what can be gleaned from most in vitro experiments; however, it is never an exact replica of a human autoimmune disease. First, studying a human disease in a highly inbred mouse model is not an ideal scenario because humans are outbred relative to mice. Thus, the study of an inbred mouse strain is roughly the equivalent of a 'single case study' in humans (Atkinson and Leiter 1999). Second, and to an even greater extent, extrapolating from an animal model to a human disease is dubious because of the genetic differences between species. There are inherent limitations in extracting pathogenic mechanisms from an animal model of disease as a result of the underlying genus- and species-specific differences that occur between an animal and a human. Under circumstances of critical importance, such as the testing of gene therapy, a species closer to humans, such as primates, may be a better candidate to serve as an experimental surrogate.

The NOD mouse as a model of human type 1 diabetes mellitus

The NOD mouse was first identified in 1980 as a useful model for investigating insulin-dependent human diabetes (Makino et al. 1980). Although the predecessor to the NOD mouse, the biobreeding (BB) rat, was identified several years earlier (Nakhooda et al. 1978), the NOD mouse gained favor and is currently the model of choice for type 1 diabetes researchers. In fact, mice are generally preferable to rats, because their genome is more familiar and analytical reagents, such as monoclonal antibodies, are more readily available (Atkinson and Leiter 1999).

Human type 1 or insulin-dependent diabetes mellitus is a $CD4^+$ and $CD8^+$ T-cell-mediated autoimmune disease that results in the targeted destruction of the insulin-secreting β cells of the pancreatic islets. Diabetic NOD mice display the biochemical and pathological characteristics of diabetes, including a lymphocyte infiltration into the pancreatic islets. Diabetes in NOD mice is heterogeneous, because its development is determined by more than 19 loci (Wucherpfennig and Eisenbarth 2001). In humans, many genetic loci are also responsible for the development of diabetes. Both NOD mice and humans have autoimmune responses to glutamic acid decarboxylase (GAD), insulin, and insulinoma-associated protein 2 (Ia2) (Taneja and David 2001).

A recent breakthrough in the study of the etiology of type 1 diabetes occurred from a comparative analysis between humans and NOD mice. Lee et al. (2001) determined that susceptibility to diabetes is conferred by a mutation in the P9 peptide-binding pocket of the MHC II molecules HLA-DQ8 and $I\text{-}A^{g7}$ in humans and NOD mice, respectively. Using X-ray crystallography, this group was able to characterize the three-dimensional structures of these molecules and determine that they lacked an aspartic acid residue at position 57 of the β chain, resulting in a net positive charge for these molecules. Functionally, the mutation in these MHC II molecules enables them to bind a different repertoire of peptides, including the immunodominant T-cell epitopes of islet antigen peptides in NOD mice (Yu et al. 2000). These results infer that type 1 diabetes in mice and humans may stem from the same antigen-presenting events. They further demonstrate the significance of the NOD mouse as an animal model of type 1 diabetes.

THE NEW ZEALAND BLACK/WHITE MOUSE AS A MODEL OF HUMAN SLE

Systemic lupus erythematosus is a systemic autoimmune disease associated with pathogenic autoantibodies. Some of these pathogenic autoantibodies include anti-DNA in glomerulonephritis, anticardiolipin in thrombosis, and anti-Ro in heart block (Lipsky 2001). The disease has been linked with several MHC genes. In fact, certain MHC alleles have been associated with the occurrence of particular autoantibodies, including HLA-DR2 and HLA-DR3 with anti-Ro and anti-La antibodies, as well as HLA-DR4 and HLA-DQ3 with anti-Sm and anti-RNP antibodies (Chernajovsky et al. 2000). Complement deficiencies, involving the complement molecules C1q, C2, and C4, have also been sited in SLE, as well as a host of other immunoregulatory defects.

The F1 hybrid cross between New Zealand black (NZB) and New Zealand white (NZW) mice generates the NZB/W mouse that is recognized as the best murine model of SLE (Drake et al. 1995). In these mice, the disease develops spontaneously and is characterized by high titers of IgG anti-DNA antibodies. Death in these animals occurs by a progressive, severe glomerulonephritis, similar to the renal destruction seen in human SLE. The development of both human and murine SLE is strongly linked with particular MHC alleles.

The NZB/W mouse model has been used to identify a myriad of abnormalities associated with the autoimmune disease SLE. This animal model was used to identify B-cell hyperreactivity as an immunoregulatory defect in SLE. On T-cell stimulation, resting B cells from these mice display increased proliferation, IgM secretion, and upregulation of co-stimulatory molecules (Jongstra-Bilen et al. 1997). Genetic loci on chromosome 1 in both parental strains NZB and NZW have been implicated in this B-cell hyperreactivity (Vyse et al. 1997; Sobel et al. 1999). This model was also used to delineate a role for cytokines in SLE pathogenesis. The F1 hybrid mouse inherits a dominant gene from the NZW parent that correlates with reduced levels of TNF-α production. The

administration of replacement TNF-α delayed the onset of lupus nephritis (Jacob and McDevitt 1988).

This model has also been used to identify multiple genetic susceptibility loci for SLE. Breeding of NZW and NZB strains has yielded a variety of strains called NZM. Using genetic mapping techniques, the analysis of these NZM strains has enabled researchers to identify susceptibility loci for SLE in this model. The analysis of congenic strains with these loci is enabling researchers to determine the functional role that these loci may have in SLE disease pathogenesis.

Strain K/BxN: a spontaneous mouse model of rheumatoid arthritis

In autoimmune disease research, an animal model can often be the framework supporting a new theory in the pathogenesis of an autoimmune disease. Occasionally, an animal model provides evidence to challenge an existing theory, such as in the case of rheumatoid arthritis (RA). RA is a chronic, inflammatory joint disease, characterized by synovial thickening and lymphocyte infiltration, as well as cartilage and bone destruction in the joint. Given the association of this disease with certain MHC II alleles, contemporary researchers believe that $CD4^+$ T cells play a crucial role in the pathogenesis of RA. Therapeutic trials were conducted with antibodies to CD4, but they were not very successful (Feldmann 2001).

Kouskoff et al. (1996) uncovered an intriguing new animal model of arthritis. This group crossed the TCR transgenic line KRNxC57BL/6 (the TCR recognizes a bovine ribonuclease peptide in the context of $I\text{-}A^k$), with the NOD strain. The resulting strain, K/BxN, has a TCR that recognizes a peptide of glucose-6-phosphate isomerase (GPI) in the context of the NOD-derived $I\text{-}A^{g7}$ (Matsumoto et al. 1999). GPI is a ubiquitously expressed protein that catalyzes reactions in glycolysis and gluconeogenesis. All of the K/BxN offspring develop a spontaneous arthritis that is strikingly similar to human RA. Although arthritis is initiated by T-cell activation in this model, joint-specific pathology is mediated by anti-GPI antibodies. In fact, transfer of antibodies can reproduce disease. This model suggests that antibodies may not merely be a phenomenon in RA; they may in fact be the primary mediators of disease.

Rodent EAE as a model of human MS

In the aforementioned animal models, disease develops spontaneously. In contrast, the rodent model of EAE is an induced model of disease. Induced models are advantageous because the onset and progression of the disease can be carefully monitored (Taneja and David 2001). The EAE rodent model is used extensively as a model for human MS. EAE can be induced with a variety of autoantigens, including MBP, PLP, and MOG, e.g. in PL/J mice, EAE is induced with the N-terminal peptide of MBP (Ac1-11). Histologically, the EAE pathology is similar to MS, although the degree of demyelination and the distribution of the lesions are different (Taneja and David 2001). In rodents, predisposition to EAE is also associated with II MHC alleles, similar to MS in humans.

The rodent model of EAE has been a powerful tool for examining important mechanisms in autoimmune disease pathology. Experiments in this model revealed that superantigens could induce relapses or exacerbate autoimmune disease (Brocke et al. 1993). This model was also used to demonstrate the concept of 'epitope spreading', as previously discussed.

Furthermore, the EAE model will invariably play an instrumental role in identifying candidate therapies for human MS, e.g. the injection of a herpes simplex virus vector driving the human fibroblast growth factor gene is reversing the pathological signs of EAE in C57BL/6 mice (Ruffini et al. 2001). Recently, Youssef et al. (2002) have identified a role for atorvastatin, a drug currently given to reduce high cholesterol, in ameliorating the disease severity in three different mouse models of EAE. On repeated administration of atorvastatin, investigators noted increased levels of anti-inflammatory cytokines, including IL-4, IL-10, and TGF-β. The EAE mouse model has also been used to test a therapeutic strategy involving the blockade of very late activated antigen-4 (VLA-4), a T-cell antigen that aids T cells in penetrating the blood–brain barrier. The results of the trial were promising because they demonstrated a reversal of paralysis and eliminated relapses in treated mice. Clinical trials are currently under way with a human antibody to VLA-4 (Steinman 2001).

AUTOIMMUNITY THROUGH IMMUNIZATION

The associations between infection and autoimmunity have accumulated rapidly in the scientific literature since the initial connection between the two was observed in the mid-1960s (Puxeddu et al. 1965). Precisely how an immune response to a pathogen evolves into an autoimmune disease remains unknown. Nevertheless, if an immune response to a pathogen may incite an autoimmune disease, perhaps an immune response to a vaccine may also elicit an autoimmune disease. Given the potential cross-reactivity between an autoantigen and a microbial antigen, could a vaccine pose the threat of priming for autoimmune disease in genetically susceptible individuals? Or could a potent vaccine adjuvant alter immunoreactivity, favoring a break in self-tolerance?

At a recent conference organized by the Fondation Merieux, Schoenfeld and Pless reported their conclusions with hesitancy (Regner and Lambert 2001). They

concluded that, despite the lack of data to make a careful assessment, it appears that the connection between immunization and autoimmune disease is weak. Furthermore, they stated that the benefits of immunization far exceed the risks (Regner and Lambert 2001). The initial assessments regarding the safety of the Lyme disease vaccine demonstrated that there were no long-term adverse effects from immunization (Poland and Jacobson 2001; Sikand et al. 2001). In another investigation, immunizing infants with a recombinant hepatitis B virus vaccine did not result in an increase in autoantibody production at a 6-year follow-up study (Belloni et al. 2002). Given the slight possibility for vaccine-induced immunization, the implications for future vaccine design are evident, e.g. a modified vaccine design may include mutating a cross-reactive epitope to preclude molecular mimicry-based autoimmunity.

TREATMENT STRATEGIES FOR AUTOIMMUNE DISEASE

Treating a patient with an autoimmune disease is an inordinately complex task. Treatment is complicated because of the heterogeneous nature of these diseases. At the cellular and molecular level, neither the etiology nor the pathogenesis of autoimmune disease is well defined. Furthermore, for a physician, autoimmune diseases may be vexing for the following reasons: they are chronic; the course of the disease may vacillate between periods of relapse and periods of remission; patients may be affected differently by the same disease; and patients often present when the disease has already progressed to tissue and organ damage (Chernajovsky et al. 2000). Treatment is initiated to reinstate 'immune homeostasis' in the autoimmune disease patient.

Autoimmune diseases are wildly diverse. Although they span the gamut of clinical manifestations, the current management of most autoimmune diseases relies on immunosuppression, including the use of corticosteroids such as prednisone, e.g. patients with RA are administered methotrexate which acts via adenosine to suppress inflammation (Chan and Cronstein 2002). The current treatment strategy for MS includes synthetic glatiramer acetate, an agent that reportedly acts by shifting the T-cell phenotype to Th2 cells (Gran et al. 2000). Generally, immunosuppression has had limited success and is often used for lack of a better alternative (Persidis 1999).

In the case of some autoimmune diseases, recent approaches to modifying the immune system have demonstrated promising clinical improvements. Sustained therapy with TNF-α blockers has been successful in arresting RA (Pisetsky 2000) and Crohn's disease (Podolsky 2002). Patients with relapsing–remitting MS have been responsive to INF-β treatment, a drug administered to inhibit lymphocyte migration to the brain (Mehindate et al. 2001; Steinman 2001). These therapeutic strategies involve immunomodulation with cytokines and cytokine antagonists. Anti-T-cell monoclonal antibodies, signal transduction blockers, and pharmacological agents have also been implemented (Tsokos and Nepom 2000).

Gene therapy is employed by researchers to develop revolutionary treatments for autoimmune disease. This cutting-edge technology is the process of inserting and expressing foreign genes into the host cell genome. Many systems utilize viral vectors as a vehicle to insert genes by transduction. Successful animal trials with gene therapy have included the treatment of RA, MS, diabetes, and lupus (Tarner and Fathman 2001). These successes have supported the clinical trial of gene therapy in humans. With an estimated disease burden of $US65 billion (Persidis 1999), arthritis has featured prominently in human gene therapy investigations. In a recent study, a gene encoding the IL-1 receptor antagonist was transferred to the metacarpophalangeal joints of patients with advanced RA (Evans et al. 1996). Synoviocytes were injected ex vivo with a retroviral vector and reimplanted into the joint. The successful completion of this trial shows promise for the further application of gene therapy (Gouze et al. 2001; Horwood et al. 2002).

CONCLUSION

Autoimmunity constitutes the sustained 'attack' of self-tissue mediated by pathogenic, self-reactive antibodies and/or lymphocytes. Autoimmune diseases are a heterogeneous collection of about 80 distinct illnesses representing a broad range of pathology. The enormous complexity associated with the etiology, mechanisms, and pathogenesis of autoimmune disease is not rivaled by any other human disease.

Autoimmunity and autoimmune disease make up a topic teeming with discrepancies: decades ago, scientists refuted the existence of a disease that is today recognized as a serious societal burden. Autoimmune disease is the erroneous attempt of an organism to protect itself as it attacks itself. The present treatment of autoimmune disease relies on immunosuppression, rendering the patient susceptible to infection and illness.

Despite the complicated, and often contradictory, nature of autoimmune disease, scientists are deftly using valuable tools to unravel autoimmunity, including experimental animal models and gene therapy. With these efforts, scientists seek to understand, as well as to reinstate, the 'immune homeostasis' that has been lost in the autoimmune response.

Genetic disorders of adaptive immunity 9
References 18

There are more than 100 recognized diseases that are genetically determined and compromise immune defenses against microorganism invasions. Mutations of 86 genes (Table 1) have so far been identified in association with as many immunodeficient conditions. Advances in genomics have helped enormously in identifying these genes. Today, the understanding of how their products contribute to the many complex reactions of different cells involved in immune defense (both innate and adaptive) contributes to a better knowledge of our immune system. This chapter reviews what we know about these conditions.

GENETIC DISORDERS OF INNATE IMMUNITY

Deficiency in granulocyte production

Inherited severe congenital neutropenia (SCN) was reported more than 40 years ago as Kostmann's syndrome (Kostmann 1956). Since then, various forms of inherited neutropenias have been described (Figure 1). When neutrophil counts are <200/mm^3 of blood, neutropenia exposes the patient to severe bacterial and fungal infections, which can spread throughout the bloodstream and cause death in the absence of appropriate treatment. The usual sites of infections are located at the interface between body cavities and the outside environment. In addition, chronic severe periodontitis is a hallmark of severe neutropenia. In most cases, Kostmann's syndrome is associated with a block in granulocyte differentiation at the promyelocyte stage. Both autosomal dominant (with variable penetrance) and autosomal recessive patterns of inheritance have been described. In recent years, it has been found that most patients with SCN carry mutations of the neutrophil elastase-2 gene (*ELA-2*) (Dale et al. 2000). The physiopathology of defective neutrophil production is still unclear, although it is thought that mutations of the elastase gene result in a premature apoptosis of neutrophil precursors (Aprikyan et al. 2001). Interestingly, cyclic neutropenia, a condition characterized by regular 21-day cycles of neutrophil counts oscillating between 0 and normal values, is also caused by mutations of ELA-2 with an autosomal dominant inheritance (Horwitz et al. 1999; Dale et al. 2000). The mechanism underlying cyclic hemopoiesis is not understood.

Recently it has been proposed that susceptibility to infections in SCN is the consequence not only of the absence of mobile phagocytic cells migrating to infected tissues, but also of defective release of antibacterial peptides such as α defensins (Putsep et al. 2002).

Other complex conditions can cause severe congenital neutropenia such as Shwachman's syndrome, which is characterized by exocrine pancreas insufficiency, and metaphyseal dysplasia with an autosomal recessive inheritance. The molecular mechanism is presently unknown, although it has recently been shown that Shwachman's syndrome is caused by mutations of the *SBDS* gene (Kyono and Coates 2002; Boocock et al. 2003). Neutropenia is also a feature of glycogenosis Ib (Kyono and Coates 2002). A gain of a function mutation

Table 1 *Genetically characterized primary immunodeficiencies*

Gene/product	Expression	Disease
Immunodeficiencies of neutrophils		
Elastase	Neutrophils	Agranulocytosis cyclic neutropenia
SBDS	Neutrophils	Shwachmann's syndrome
WASP (activating mutation)	Leukocytes	Agranulocytosis
β_2-Integrin	Leukocytes	LAD-I
GDP fucose transporter	Leukocytes/endothelial cells	LAD-II
β-A	Neutrophils	Neutrophil actin dysfunction
Rac-2	Neutrophils	LAD variant
C/EBPϵ	Neutrophils	Specific granule deficiency
CyBB (gp91 cytochrome *b*)	Phagocytic cells	XL CGD
CyBA (gp22 cytochrome *b*)	Phagocytic cells	AR CGD
NFC1 $p47^{phox}$	Phagocytic cells	AR CGD
NFC2 $p67^{phox}$	Phagocytic cells	AR CGD
G6PD	Phagocytic cells	CGD-like syndrome
Cathepsin C	Neutrophils (?)	Papillon–Lefèvre syndrome
Plasma proteins		
Classic pathway, of complement C1q, -r, -s, C4, C2	Plasma	Infections by encapsulated bacteria

Table 1 *Genetically characterized primary immunodeficiencies (Continued)*

Gene/product	Expression	Disease
RFXANK/B	Antigen-presenting cells	HLA-II deficiency
RFX 5	Antigen-presenting cells	
RFX AP	Antigen-presenting cells	
TAP-1	Antigen-presenting cells	HLA-I deficiency
TAP-2	Antigen-presenting cells	
Immunodeficiencies with genomic instability		
DNA ligase IV	Lymphocytes	Combined immunodeficiency
DNA ligase I	Lymphocytes	Combined immunodeficiency
ATM	Lymphocytes	Ataxia telangiectasia (AT)
MRE-11	Lymphocytes	AT-like disorder
NBS I/Nibrin	Lymphocytes	Nijmegen breakage syndrome
DNMT 3B	Lymphocytes	ICF syndrome
BLM	Ubiquitous	Bloom syndrome
Immunodeficiencies with bone disease		
RMRP	?	Cartilage hair hypoplasia
SMARCAL	?	Schimke immuno-osseous dysplasia
Other immunodeficiencies		
WASP	Hemopoietic cells	Wiskott–Aldrich syndrome
CD40L	T lymphocytes	Hyper-IgM syndrome type 1
CD40	B lymphocytes, dendritic cells	Hyper-IgM syndrome type 3
T/NK cytolytic deficiencies		
Perforin	T/NK cytolytic cells	Lymphohistiocytosis
LYST	Ubiquitous	Chédiak–Higashi syndrome
RAB27a	Cytolytic cells, melanocytes	Griscelli's syndrome
SAP/SH2DIA	Lymphocytes	XLP–Purtilo syndrome
Miscellaneous		
AIRE	Thymic epithelial cells	APECED (candidiasis/autoimmunity)
B-cell immunodeficiencies		
μ Heavy chain	B-cell precursors	
Igα	B-cell precursors	
λ5	B-cell precursors	AR agammaglobulinemia
BLNK	B-cell precursors	
BTK	B-cell precursors	XL agammaglobulinemia
AID	B cells (germinal centers)	Hyper-IgM syndrome type 2
IgHγ1	B cells	IgG1 deficiency
IgLK	B cells	IgK deficiency

APECED, polyendocrinopathy–candidiasis–ectodermal dystrophy; AR, autosomal recessive; AT, ataxia telangiectasia; CGD, chronic granulomatosis disease; G6PD, glucose-6-phosphate dehydrogenase; ICF, immunodeficiency centromeric facial; IL, interleukin; LAD, leukocyte adhesion deficiency; MBL, mannose-binding lectin; NK, natural killer; SCID, severe combined immunodeficiency; XL, X-linked.

of the *WASP* gene is causing an X-linked form of SCN (Devriendt et al. 2001). Therapy by administration of granulocyte colony-stimulating factor (G-CSF) is efficient in most forms of SCN (Devriendt et al. 2001). Kostmann's syndrome as well as Schwachman's syndrome predispose to myeloid leukemia. In the former setting, leukemia is often associated with the acquisition of somatic mutations of the intracellular region of the G-CSF receptor (Dale et al. 1993; Tidow et al. 1997; Devriendt et al. 2001). The mechanism of this predisposition is unknown. It is, however, suspected that enhanced precursor proliferation caused by premature daughter cell death could favor secondary genetic alterations.

Disorders of neutrophil function

MIGRATION: LEUKOCYTE ADHESION DEFICIENCY

Neutrophils migrate to tissues from blood vessels upon appropriate inflammatory signaling. Molecules involved in the process of adhesion and migration have now been characterized in part because natural mutants of neutrophil adhesion/migration have been described. These are called leukocyte adhesion deficiency (LAD).

LAD-I, a rare autosomal recessive disorder, is characterized by accumulation of neutrophils in the bloodstream whereas infection sites are devoid of pus. Severe,

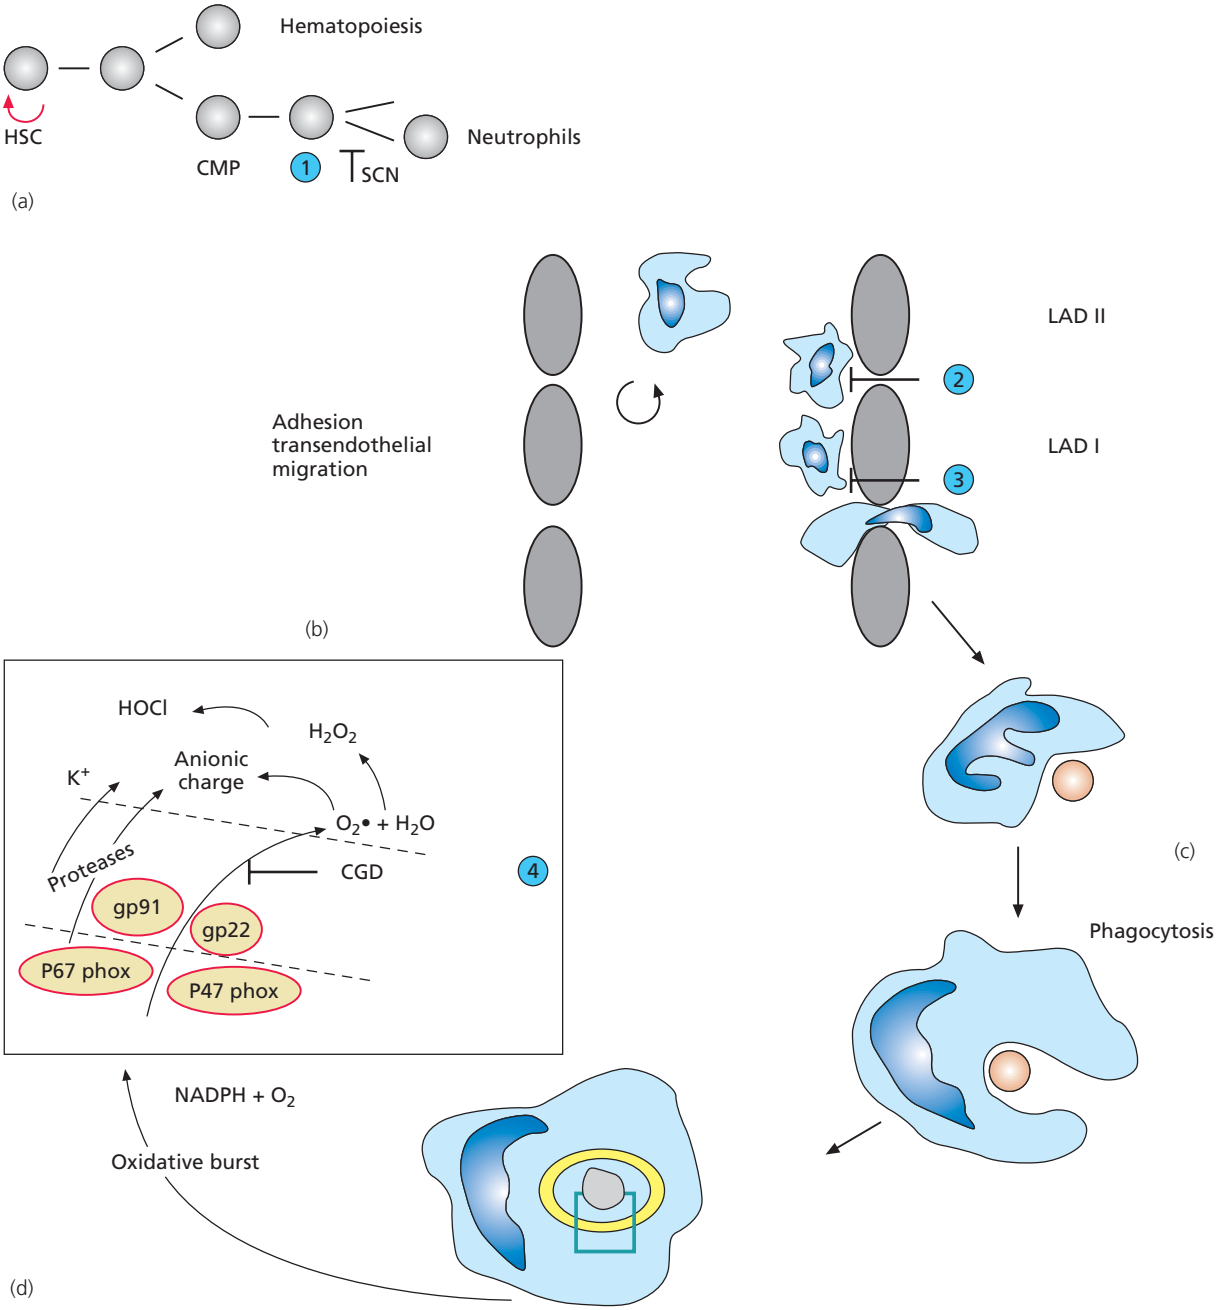

Figure 1 *Main phagocytic cell disorders.* **(a)** *Hemopoiesis. HSC, hemopoietic stem cells with self-renewal capacity; common myeloid progenitors. Neutrophil development from myeloid progenitors is impaired in severe congenital neutropenia (SCN) and cyclic neutropenia (CN) caused by elastase mutations (1).* **(b)** *Adhesion to endothelial cells and transendothelial migration of neutrophils. Rolling of neutrophils is abrogated in leukocyte adhesion deficiency II (LAD-II) (2). β_2-integrin-mediated adhesion and transendothelial migrations are blocked in LAD-I (3).* **(c)** *Phagocytosis.* **(d)** *Oxidative burst (magnification in inset). Once microorganisms are phagocytosed, activation of membrane NADPH oxidase composed of four subunits leads to superoxide production, then H_2O_2 after superdismutase action and HOCl (chlorination). In addition, the induced anionic charge triggers a K^+ influx and bacteriolytic protease release into the phagolysosome. Deficiency in any component of NADPH oxidase causes a chronic granulomatous disease (CGD) (4). CMP, common myeloid progenitor.*

unabated, bacterial infections, mostly of soft tissues, ensue, lead to extensive necrosis (Anderson et al. 1985; Fischer et al. 1988). LAD-I is also often associated at birth with delayed loss of the umbilical cord and omphalitis. The absence of pus and leukocytosis led to the suspicion that neutrophils were unable to adhere to and/or migrate along a chemotactic gradient. This was indeed proved to be the case in vitro and in vivo. It was recognized that expression of heterodimeric molecule complexes was defective at leukocyte membranes, i.e.

β_2-integrins including $\alpha_L\beta_2$ (LFA-1), $\alpha_M\beta_2$ (MAC-1), and $\alpha_x\beta_2$ (p150, 95) molecules. Mutations of the gene encoding the β_2-integrin subunit cause this disorder (Kishimoto et al. 1987). Null mutations result in severe life-threatening leukocyte adhesion deficiency whereas missense mutations enabling residual β_2-integrin expression and function are compatible with life, although severe bacterial infections can occur. β_2-integrins are involved in leukocyte adhesion to the endothelial wall and then transendothelial migration after activation of β_2-integrins by chemokines. β_2-integrins bind to intercellular adhesion molecule 1 (ICAM-1) at endothelial surfaces and also iC3b on bacterial surfaces. It is thought that this condition is primarily a neutrophil dysfunction because other leukocytes such as monocytes can use the $\alpha_4\beta_1$-integrin not expressed by neutrophils to compensate for the β_2-integrin deficiency.

Variants characterized by the presence of a nonfunctional β_2-integrin have been described. In these cases, inside-out signaling leading to β_2-integrin activation was shown to be impaired (Kuijpers et al. 1997; Harris et al. 2001). More recently, a third similar case has been reported (Mcdowall et al. 2003). In the latter not only β_2- but also β_1- and β_3-integrins were disabled despite normal structure and expression of these molecules. A bleeding disorder was therefore also present because β_3-integrin is involved in platelet aggregation. The molecular basis of this impaired β-integrin activation is unknown. However, these findings point remarkably to the role of inside-out signaling in driving neutrophil activation to adhere to and migrate toward infectious zones.

LAD-II

Etzioni et al. (1992) have reported a similar condition associated with a dysmorphic syndrome, failure to thrive, and learning disability. This autosomal recessive condition has been found in a very small number of patients so far. There is a lack of expression of the H antigen by erythrocytes (Bombay phenotype) and a defect of leukocytes to migrate from blood. This condition is the consequence of a fucosylation defect (Luhn et al. 2001), which leads to a defective formation of the sialyl Lewis X (sLe^x) carbohydrate, the selectin ligand (L-, E-, and P-selectins). Therefore, the rolling process mediated by repeated short interactions between leukocytes and endothelial cells does not occur properly, impairing the further step of adhesion.

NEUTROPHIL ACTIN DYSFUNCTION

A small number of patients have been reported with a condition characterized by recurrent bacterial and fungal infections associated with abnormal neutrophil movement, whereas β_2-integrins are normally expressed (Luhn et al. 2001). There is decreased actin polymerization in neutrophils in one case, associated with a decrease in a 89-kDa protein expression and an increased expression in leufactin, a protein interacting with F-actin (Coates et al. 1991). A dominant β-actin mutant has been found in another child with a similar syndrome (Nunoi et al. 1999).

RAC-2 DEFICIENCY

In two patients with severe bacterial infections, poor wound healing, and leukocytosis, neutrophils were found to be unable to move along a chemotactic gradient, and also unable to produce superoxide anion when stimulated with the bacterial peptide flmp. These patients were shown to exhibit Rac-2 gene mutation. Rac-2 is a Rho guanosine triphosphatase (GTPase) involved in induction of actin polymerization, integrin complex formation, and activation (Ambruso et al. 2000; Williams et al. 2000).

SPECIFIC GRANULE DEFICIENCY

This rare condition results from the combination of defective chemotaxis with a deficiency in lysosomal proteins such as defensins and lactoferrin. Clinical phenotype is characterized by recurrent bacterial and fungal infections. Specific granules are lacking in neutrophils. Mutations of the transcription factor (CCAAT) enhancer-binding protein (C/EBPϵ), which controls granule protein synthesis, are causing this condition (Lekstrom-Himes and Xanthopoulos 1999).

OXIDATIVE BURST: CHRONIC GRANULOMATOUS DISEASE

Phagocytic cells generate reactive oxygen species by the enzyme nicotinamide adenine dinucleotide phosphate (NADPH) oxidase. The enzyme catalyzes the oxygen reduction to superoxide which can be further transformed to H_2O_2 and, by the myeloperoxidase, to HOCl. These reactive oxygen species (ROS) generated in the membrane of phagolysosomes on activation are thought to play a major role in the killing of engulfed bacteria and fungi by neutrophils and macrophages. This is best demonstrated by chronic granulomatous disease (CGD) in which this generation of ROS is defective. Its incidence is estimated at 1:250 000 live births (Winkelstein et al. 2000). Four molecular defects have been characterized (Segal et al. 2000):

1. deficiency in gp91, a membrane cytochrome *b* component encoded by an X-linked gene (*CYBB*) which is defective in 70 percent of cases
2. deficiency in gp22, a second subunit of cytochrome (CYBA) accounting for 5 percent of CGD
3. $p47^{phox}$ (*NFC1* gene), a cytosolic protein that associates to the cytochrome on neutrophil stimulation; its deficiency accounts for about 20 percent of CGD
4. the $p67^{phox}$ (*NFC2* gene), another cytosolic component binding the cytochrome on activation (5 percent of CGD).

Patients with autosomal recessive CGD tend to have a slightly milder phenotype. CGD is characterized by bacterial infections, mostly as abscesses located in lymph nodes, liver, lung, and bones – all tissues or organs rich in macrophages. Typically, catalase-positive bacteria (which destroy endogenously produced H_2O_2), *Staphylococcus aureus*, *Serratia marcescens*, *Burkholderia cepacia*, and fungi (*Aspergillus* species) are the most frequently encountered pathogens. Of note, non-infectious granuloma can develop in various sites associated with varyingly severe consequences, such as bladder obstruction, pyloric stenosis, colitis, or chronic interstitial pneumonitis. Infections result in a 2.5–5 percent death toll/year of affected patients (autosomal recessive and X-linked form, respectively) (Winkelstein et al. 2000).

The physiopathology concept of this condition has been challenged by Segal and coworkers who proposed, as based on mouse models, that ROS generation is creating an increased anionic charge compensated by entry in a pH-dependent manner of K^+ ions. The rise in ionic strength is stimulating release of proteases, which are possibly responsible for the killing of microorganisms and degradation of debris (Reeves et al. 2002). The same authors have recently shown that catalase-positive and -negative strains of *S. aureus* are equally virulent in CGD mice models, further suggesting that H_2O_2 and chlorinated reagents might not be the primary killer effectors (Messina et al. 2002), thus challenging previous views.

Myeloperoxidase deficiency is a fairly frequent condition, which results in impaired production of chlorinated reagents within phagolysosomes (Nauseef 1990). Interestingly enough, it is mostly an asymptomatic setting except in individuals with diabetes who are prone to candida abscesses (Cech et al. 1979), an observation perhaps further reinforcing Segal's view on how phagocytes kill microorganisms.

NEUTROPHIL GLUCOSE-6-PHOSPHATASE DEHYDROGENASE DEFICIENCY

In very rare patients, the most severe glucose-6-phosphatase dehydrogenase (G6PD) deficiencies lead not only to hemolytic anemia but also to a CGD-like phenotype because G6PD (Mamlok et al. 1987) catalyses the production of NADPH, the required substrate of NADPH oxidase.

The above-mentioned Rac-2 deficiency can also be regarded as an oxidative burst deficiency because Rac-2 is involved in the activation of oxidase activity.

PAPILLON–LEFÈVRE SYNDROME

Papillon–Lefèvre syndrome is characterized by a palmoplantar keratosis associated with a severe periodontopathy and, sometimes, pyogenic liver abscesses. This autosomal recessive disorder is caused by mutations in the cathepsin C gene (Toomes et al. 1999). Cathepsin C processes other proteases, such as granzymes, and may be required in the maturation of proteases necessary to bacterial killing.

A DEFICIENCY OF UNKNOWN MECHANISM: THE HYPER-IGE SYNDROME

The hyper-IgE syndrome (HIES) or Job's syndrome is a rare condition with autosomal dominant inheritance characterized by the association of a dysmorphic syndrome (coarse facies), tooth abnormalities, osteoporosis, and a unique phenotype of susceptibility to infections (Grimbacher et al. 1999a).

These patients suffer from childhood with lung abscesses, and skin, soft tissue, and bone infections associated with very mild inflammatory reaction ('cold abscesses'). *S. aureus* and fungi are the most frequently encountered microorganisms. In the lungs, pneumatoceles are formed as both sequelae and sites of new infections. In most textbooks, HIES is classified as a neutrophil disorder because it has been shown that there is a mild neutrophil chemotaxis disorder in this condition. It is far from clear that this poorly reliable finding contributes to the understanding of HIES physiopathology. There is an HIES locus on chromosome 4 and, so far, almost nothing is known about disease mechanisms (Grimbacher et al. 1999b). The biological hallmark of HIES is an elevated IgE serum level which can be very high in young children (>40 000 IU/ml) and tend to diminish with age, although susceptibility to infections persists. It is thus not known whether hyper-IgE is involved in pathogenesis or is just a surrogate marker. Mystery has been further reinforced by the observation that allogeneic hemopoietic stem-cell transplantation does not cure the disease (Gennery et al. 2000), a finding that suggests that abnormal cells are not of hemopoietic origin. It is thus highly likely that HIES should not in the future be classified within the neutrophil dysfunction chapter!

Disorders of plasmatic proteins

The complement cascade (Figure 2) plays an important role in the early steps of defense against pathogens (preimmune step) as well as in immunized individuals. Actually, most of our understanding of the role of the complement system relies on the identification of the natural defects of almost every one of its components (Walport 2001a, 2001b). The complement system can be activated by three mechanisms, i.e. the classic pathway usually triggered by antigen–antibody complexes, mediated by C1q, -r, -s, and C4 and C2, the alternate pathway triggered by microbial surfaces, mediated by C3, B, and D factors and properdin, and the lectin pathway induced by the mannose-binding lectin (MBL). All three result in C3 activation by cleavage into the C3b opsonin. Also, C3b triggers the formation of the membrane attack complex (MAC) formed by C5–9 components. Deficiencies of C3 activation inhibitors (H and I, which cause a C3 depletion), as well as of the classic and the alternate pathway,

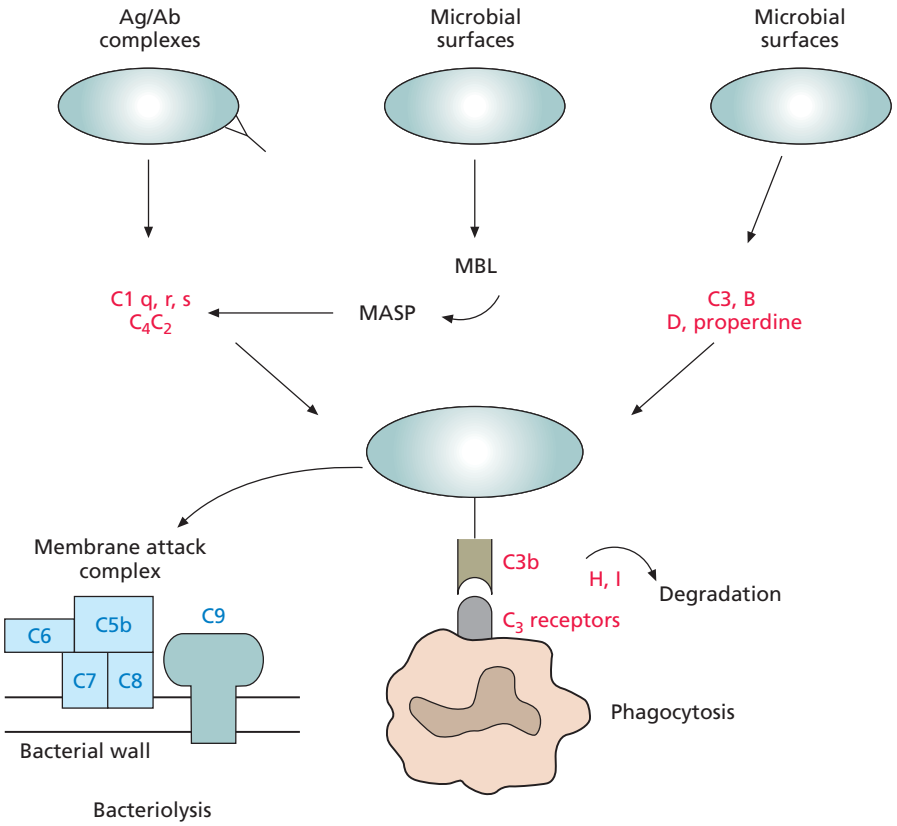

Figure 2 *The complement system. C1q, -r, -s and C4, C2, H, I, C3, B, D: encapsulated bacteria; C5, C6, C7, C8, C9: gram-negative bacteria,* Neisseria meningitis.

except for properdin deficiency, all result in infections by encapsulated bacteria such as *Streptococcus pneumoniae*, *S. pyogenes*, and *Haemophilus influenzae*. Infection can be blood borne or localized to the respiratory tract. These findings underline the role of C3b in facilitating opsonization of encapsulated bacteria. C3 deficiency tends to have more severe consequences given its central role. X-linked properdin deficiency is a very rare condition leading in most cases to fulminant meningitis caused by *Neiserria meningitidis* from the unusual strains y and w135. MBL deficiency may be a susceptibility factor for bacterial and candida infections, although this is still debated (Summerfield et al. 1995). Deficiencies from factors of the MAC lead to susceptibility to infection by *Neisseria* spp., particularly *N. meningitidis*, emphasizing the role of MAC-mediated bacteriolysis in the control of this class of bacteria.

Complement deficiencies are also associated with autoimmune manifestations (systemic lupus erythematosus, vasculitis, glomerulonephritis) because of the role of the complement system in the clearance of antigen–antibody complexes and apoptotic bodies.

Congenital asplenia

Congenital absence of spleen can be rarely observed either as one of the manifestations of situs abnormalities – Ivemark syndrome caused by mutations of the Connexin 43 gene (Britz-Cunningham et al. 1995) or the X-linked *ZIC3* gene (Gebbia et al. 1997) – or as an isolated condition with an autosomal dominant inheritance and variable penetrance. Its cause is still unknown. This condition exposes the individual to fulminant, blood-borne infections caused by encapsulated bacteria, mostly *S. pneumoniae*, thought to be the consequence of the defective splenic macrophage filter.

Undescribed deficiencies of innate immunity

It has now been well established that receptors for structures not expressed by eukaryotes are present in phagocytic and other cells. Toll-like receptors are the most salient example. They serve to signal dangers, induce innate immune response mostly through activation of the factor NFκB, and link innate to adaptive immunity (Barton and Medzhitov 2002). A mouse natural mutant of Toll-R4 has been described and characterized by an absence of response to lipopolysaccharide (LPS), its main ligand (Poltorak et al. 1998). A number of knockout (KO) mice in which a given Toll receptor or associated signaling molecule is absent have been engineered and found to be susceptible to different classes of pathogens. Surprisingly, no human counterpart has yet been

described. It is not known whether this can be explained by unexpected redundancy between receptors and/or associated signaling pathways, or whether they are very rare conditions.

Nevertheless, Galin et al. reported a single case of a patient with defective cytokine production on bacterial challenge associated with bacterial infections and limited inflammatory response (Kuhns et al. 1997). This syndrome, not yet molecularly characterized to our knowledge, is a good candidate to represent a first example of a Toll receptor pathway deficiency.

NEMO/IKKγ deficiency

NEMO deficiency results in a complex syndrome in which both innate and adaptive immune responses are defective (Zonana et al. 2000; Doffinger et al. 2001; Jain et al. 2001). NEMO is a regulatory element, which forms, together with IKKα and -β, the kinase required to phosphorylate and therefore induced ubiquitinylation of NFκB inhibitors (IκBα), thus enabling NFκB complexes to migrate to the nucleus and exert their transcriptional activity (Courtois et al. 2001). NEMO deficiency can impair responses to cytokines such as interleukin (IL) 1 and tumor necrosis factor (TNF) and also potentially some of the Toll-like receptors. This is, however, a more complex syndrome because NFκB is, for instance, also involved in mediating CD40-induced signals in B lymphocytes; thus NEMO deficiency can result in impaired antibody production. These patients present predisposition to infections with encapsulated bacteria but also mycobacteria in more severe cases. It is thus difficult to distinguish which pathway perturbation is responsible for a given type of infection. There is heterogeneity in the consequences of mutations of the NEMO gene (knowing that null mutations are lethal), which adds to the complexity of the analysis.

As NFκB is also involved in signaling from cells outside the immune system, patients may variably present with anhidrotic ectodermal dysplasia, lymphedema, and osteopetrosis.

Natural killer cells

Natural killer (NK) cell function lies at the border of innate and adaptive immunity. The role of NK cell-mediated defense against infections is not yet well known although recent evidence for a role in resistance to cytomegalovirus (CMV) associated with the Ly-49H molecule in mice has been provided (Brown et al. 2001). No such information has yet been obtained from studies on human immunodeficiencies. A single case of NK cell deficiency has been reported. It has been found associated with recurrent infections of the herpes virus group (Biron et al. 1989). However, no molecular mechanism has been described. In addition, recurrent infections, notably with herpes simplex virus, have been described associated with decreased blood NK cell counts and a modified FcγRIIIA (CD16) receptor. Relationship to pathogenesis has not, however, been firmly established (de Vries et al. 1996; Jawahar et al. 1996). Of note, NK cell cytotoxicity impairment, found in patients with perforin deficiency (together with cytolytic T-cell function impairment), is associated with an entirely distinct phenotype (see below).

Susceptibility to human papilloma virusinfection

In rare families, mutations of either of two genes, *EVER-1* and *EVER-2*, have been reported to predispose to infection, with an autosomal recessive inheritance to epidermodysplasia verruciformis (EV). EV consists of chronic skin infection caused by certain strains of human papilloma virus (HPV), e.g. HPV-5, and predisposing to squamous cell carcinomas (Ramoz et al. 1999, 2002). This is a rather unique setting, because these conditions do not create a susceptibility status for other microorganisms. *EVER-1* and *EVER-2* gene products are expressed among other cells in keratinocytes – the target cell of HPV – and could thus probably interfere locally with viral persistence. This is a privileged setting to analyze further local immunity to HPV. It stresses that the genetic susceptibility factor for infections may not be associated with the classic arms of the immune system.

GENETIC DISORDERS AT THE INTERFACE BETWEEN INNATE AND ADAPTIVE IMMUNITY

Susceptibility to mycobacterial infections

In recent years, it has been determined that several conditions are associated with a Mendelian susceptibility to nonpathogenic mycobacterial infection and to some extent to salmonella infections (Casanova and Abel 2002; Ottenhoff et al. 2002). It turned out that all of them impair the IL-12/interferon-γ (IFN-γ) pathway known to be a major inducer and effector of so-called T-helper 1 responses (Figure 3). In about 100 such patients, it was determined that deleterious mutations of IL-12B (IL-12 p40 subunit) (Altare et al. 1998b), IL-12RB1 (IL-12 receptor β subunit) (Altare et al. 1998a), interferon γ receptor β_1 subunit (IFNGR1) (Jouanguy et al. 1996; Newport et al. 1996), IFNGR2 (interferon γ receptor β_2 subunit) (Dorman and Holland 1998), or STAT-1 (transcription factor mediating interferon-induced signaling) (Dupuis et al. 2001) were found.

Clinical severity varies according to several parameters, i.e. type of mutated genes, type of mutations

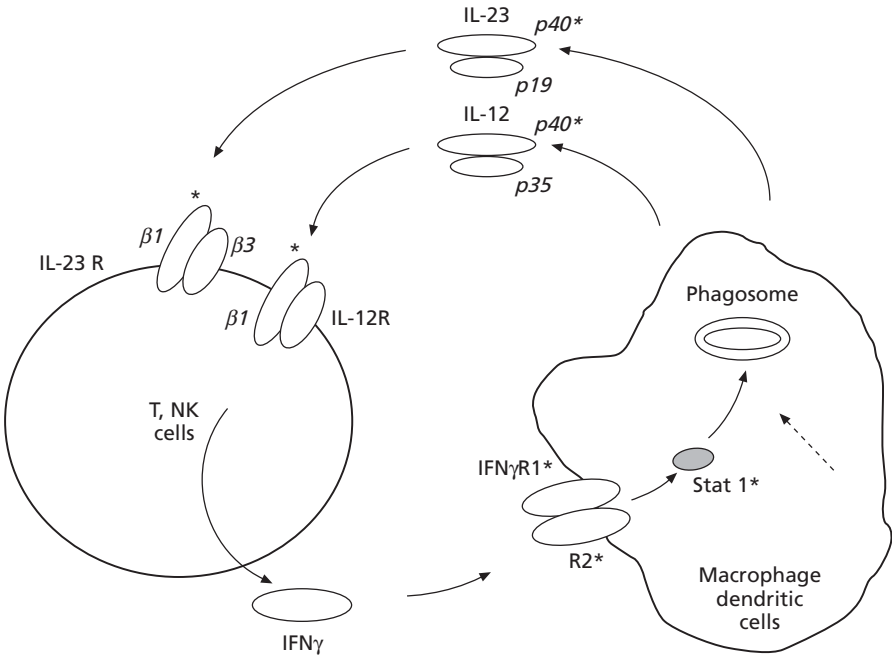

Figure 3 *The interleukin 12/interferon γ (IL-12/IFNγ) axis and its defects. *Described deficiencies. Other elements of the pathway are not shown for sake of simplification. The dotted arrow in the macrophage indicates other components of antimycobacterial immunity unrelated to IFNγ.*

from null to missense mutations, and probability to be infected with nonpathogenic mycobacteria. Associated genetic susceptibility factors could potentially also be involved. Both autosomal recessive and dominant (IFNGR1, STAT-1) inheritance patterns have been described. There are some differences in clinical presentation according to the affected genes. Complete IL-12 and IL-12RB1 mutations tend to lead to less severe mycobacterial infections with a reduced lethality compared with complete IFNGR1 deficiency. In the latter case, there is a heavy toll of early mortality caused by disseminated nonpathogenic mycobacterial infections (BCG or environmental) with a characteristic feature of the absence of typical granulomas around infected macrophages (Pierre-Audigier et al. 1997). It is possible that in the IL-12 axis deficiency, a partial IFN-γ production is preserved, accounting for a milder phenotype. In contrast, deficiency of the IL-12RB1 predisposes not only to mycobacterial infections but also to infection with *Salmonella* spp., a rather uncommon finding in IFNγR1/2 deficiencies. This suggests an additional role of IL-12 in immunity toward *Salmonella*.

A surprising hallmark of these syndromes is the rarity of infections caused by other opportunistic infections such as *Pneumocystis carinii* or *Toxoplasma gondii* and of viral infections, which were observed in only two cases. This contrasts sharply with the known susceptibility of IFNγ-deficient mice to virus challenges. No good explanation can as yet be proposed to account for this apparent discrepancy. Study of Mendelian susceptibility to mycobacterial infections has been determinant in pointing to the major and somewhat selective role of the IL-12/IFNγ pathway in the control of mycobacterial infections in humans. As this condition has also been found in a number of patients without defects in IL-12/IFNγ cytokine/receptor, more remains to be learnt about it. It is also not known whether mutations of these genes with milder consequences, could represent susceptibility elements in multifactorial risk factors for *M. tuberculosis* or *M. leprae*, in addition to the few described such as HLA-II, NRAMP1, and as yet undefined loci (Cooke and Hill 2001; Casanova and Abel 2002; Ottenhoff et al. 2002). In other words, do these Mendelian conditions represent the extreme of a more common spectrum of susceptibility?

GENETIC DISORDERS OF ADAPTIVE IMMUNITY

T lymphocytes

Since the 1960s, the central role of T lymphocytes in adaptive immunity has been recognized. The observation of patients in whom no thymus could be detected (Good 2002) brought a significant contribution to that understanding. Since then, a number of rare conditions characterized by defective T-cell development have been described, including intrinsic abnormalities defined as severe combined immunodeficiency (SCID) and environmental abnormalities related to thymic defects.

SEVERE COMBINED IMMUNODEFICIENCY

Strictly defined, SCID represents a group of rare conditions (about $1{:}10^5$ births) characterized by a complete absence of mature T cells. The presence of circulating maternal T cells, which cannot be rejected, or the presence of autologous T cells in 'leaky' phenotypes can sometimes be misleading (Buckley 2000; Fischer 2000). Absence of functional T cells is incompatible with life beyond the first year, emphasizing the major role of adaptive immune response in humans living in a normal environment.

Patients, after a 2- to 3-month latency, become prone to fungal infections, multiple viral infections in particular causing protracted diarrhea and infections resulting from opportunistic agents such as *Pneumocystis carinii*. Interstitial pneumonitis caused by *P. carinii* is actually the most frequent infection leading to diagnosis (Buckley et al. 1997). Also, live vaccines such as BCG can lead to an overwhelming infection with lethal consequences (Stephan et al. 1993). As a result of the absence of T cells, B cells, when present, are also nonfunctional. Multiple SCID phenotypes have been described according to associated lymphocytic (NK, B lymphocytes) or myeloid defects, inheritance pattern and, more recently, molecular analysis (see Figure 4). They result either from defective signaling through γc-dependent cytokine receptors (γc, JAK-3, and IL-7Rα specific for the IL-7 receptor) blocking T-cell development before T-cell receptor β (TCRβ) gene rearrangement (Sugamura et al. 1995). A purine metabolism pathway deficiency, i.e. adenosine deaminase deficiency (ADA), which leads to dATP accumulation in lymphocyte precursors and premature cell apoptosis (Hershfield and Mitchell 1995), or from defective V(D)J rearrangements of T- and B-cell antigen receptor genes. The lymphoid-specific *Rag-1* or *Rag-2* genes can be mutated as well as the Artemis gene, which encodes a member of the nonhomologous end-joining repair pathway as the DNA-dependent protein kinase, the abnormal element of severe combined immunodeficient mice (Schwarz et al. 1996; Moshous et al. 2001). The other forms of SCID (reticular dysgenesis and CD45 deficiency) are extremely rare. There are no major differences in predisposition to infections according to the different phenotypes.

Atypical forms of SCID have been described as a cause of leaky phenotype related to mutations with milder consequences or, in a few cases of ADA and γc deficiencies, to a spontaneous reverse mutation in a T-cell precursor. Some mutations of the γc gene enable T-cell development whereas T-cell functions are impaired (but not absent). In some cases, responses to certain γc-dependent cytokines are more affected than others. It results in prolonged survival with occurrence of infections usually after 2–5 years of life. Missense mutations of *Rag-1* and *Rag-2* enabling residual recombinatorial activity can result in the emergence of expanded T-cell clones found in the so-called Omenn syndrome (Villa et al. 1998). Although these patients exhibit the same susceptibility pattern to infections as typical SCID, they, in addition, suffer from immunopathological lesions caused by T-cell infiltration of the skin, gut, and other organs. Recently, hypomorphic Artemis mutations were also shown to cause genomic instability predisposing to lymphomas, although the severity of the immunodeficiency is relatively milder compared with typical SCID (Moshous et al. 2003).

THYMIC DEFECTS

DiGeorge syndrome

DiGeorge syndrome consists of an embryopathy variably associating with conotruncal heart malformation, hypoparathyroidy, a dysmorphic syndrome, and an immunodeficiency. The last results from a defective migration of the

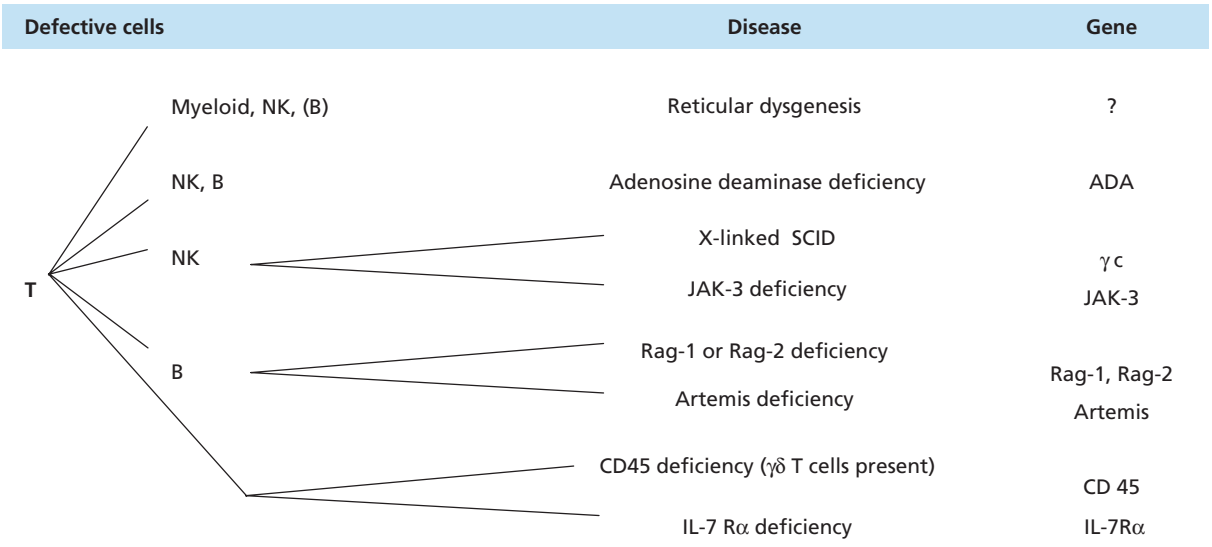

Figure 4 *Severe combined immunodeficiencies (SCID). IL, interleukin; NK, natural killer*

third and fourth embryonic branchial arches, which initiate the formation of the thymic gland (Perez and Sullivan 2002). In the rare cases where the thymic defect is complete (about 1 percent of patients with DiGeorge syndrome), patients have virtually no mature T cells in the periphery, showing that extrathymic T-cell differentiation is very limited in humans. Some patients can nevertheless develop oligoclonal T-cell populations in the periphery. In this setting, clinical consequences are as severe as those of SCID conditions. More frequently, T-cell counts are >500/mm^3 of blood and patients are not prone to infections, although late B-cell immunodeficiency and autoimmune manifestations have been occasionally reported (Perez and Sullivan 2002). The most frequent genetic defect found in patients with DiGeorge syndrome consists of hemizygous interstitial deletions of chromosome 22q11 (Carey et al. 1992; Wilson et al. 1992). There is no correlation between phenotype and genotype because some carriers of a same deletion can be very mildly symptomatic whereas others exhibit a full-blown DiGeorge syndrome including profound T-cell lymphocytopenia. There are several candidate genes located within the deletion which usually spans a 250-kb segment of DNA, TBX1, encoding a transcription factor, and *CRKOL* and *UFD1L* genes are expressed in the branchial arches during embryogenesis (Schinke and Izumo 2001). It is nevertheless unclear whether the phenotype can result from deletion of a single gene. Interstitial chromosome 10q deletion has also been rarely reported with DiGeorge syndrome. Interestingly, it has been recently shown that human leukocyte antigen (HLA)-incompatible, newborn thymic transplantation can lead to the development of functional T cells (Markert et al. 1999). These results imply that both positive and negative selection of thymocytes can be mediated by (recipient) bone marrow-derived cells. Also, expansion of HLA-identical peripheral T cells can be of benefit to DiGeorge syndrome patients with severe immune deficiency.

Nude phenotype

In one Italian kindred, a severe T-cell immunodeficiency has been found in association with baldness. This phenotype, highly reminiscent of nude mice, led to the finding of mutations in the *WHN* (winged-helix-nude gene) (Frank et al. 1999). The *WHN* gene is also mutated in the murine counterpart. It encodes a transcription factor expressed in epithelial cells of skin and thymus. Its defect impairs formation of the thymic microenvironment required for T-cell development because *WHN* induces expression of important genes in the program of thymic epithelial cell differentiation.

OTHER T-CELL IMMUNODEFICIENCIES

There are a number of primary immunodeficiencies associated with the detection of T cells in the periphery with variable functional defects. They all create a severe predisposition to infections, particularly to viruses, often associated with inflammatory bowel disease and autoimmune manifestations (Berthet et al. 1994).

Purine nucleoside phosphorylase

Purine nucleoside phosphorylase (PNP) deficiency is a rare cause of immunodeficiency with autosomal recessive inheritance. It is a purine metabolism error preventing conversion of guanine and leading to the toxic accumulation of dGTP in T-cell precursors. The immunodeficiency is often detectable after several years of life. Autoimmunity is a very frequent associated finding, together with a primary neurodevelopmental delay (Aust et al. 1992).

CD3 deficiencies

Four cases from three families with an immunodeficiency related to defect in CD3 components have been described. Although T-cell counts are within normal range, reduced expression of the TCR/CD3 complex was found associated with low CD8 T cell counts in two patients. Proliferation capacity of T cells driven by anti-CD3 antibody was low whereas antigen-induced responses were partially preserved. In one family, heterozygous mutations of the *CD3ϵ* gene were found whereas, in the other two, distinct mutations of the *CD3γ* gene were identified (Perez-Aciego et al. 1991; Soudais et al. 1993). Patients suffer from variable manifestations from bacterial lung infections to severe autoimmunity.

ZAP-70 deficiency

T-cell activation via the TCR leads to src kinase activation immediately followed by recruitment and activation of the ZAP-70 kinase, which binds to the immunoreceptor tyrosine-based activation (ITAM) motifs of CD3ζ.

A small number of patients with a complete ZAP-70 deficiency have been described (Arpaia et al. 1994; Elder et al. 1994). The clinical phenotype is severe, characterized by early onset of severe opportunistic infections, almost as in SCID patients. Surprisingly, the immunological phenotype is characterized by a selective CD8 T-cell lymphocytopenia. Nevertheless, ZAP-70-deficient CD4 T cells cannot be activated either in vitro or in vivo by antigens.

Other ill-defined severe T-cell deficiencies have been reported, including phenotypes of calcium influx deficiency (Le Deist et al. 1995), functional p56 lck deficiency (Goldman et al. 1998), and defects in cytokine production (Castigli et al. 1993).

IL-2 receptor α chain deficiency

In a single patient, a partial T-cell immunodeficiency has been found in association with lymphoid infiltration in

various organs. This immunodeficiency is caused by defective expression of the IL2-Rα chain (Sharfe et al. 1997). It combines inappropriate T-cell response to infectious agents as well as the lymphoproliferative syndrome, possibly related to defective T-lymphocyte apoptosis.

Caspase 8 deficiency

A homozygous caspase 8 deficiency has recently been described in two patients from a single kindred. There is, as expected, a defect in lymphocyte apoptosis and homeostasis, but, surprisingly, there is also an activation deficiency of T, B, and NK lymphocytes (Chun et al. 2002). It resulted in the occurrence of infections, i.e. recurrent herpes simplex virus infections, pneumonia, and chronic diarrhea. This observation reveals an unexpected, yet poorly understood, role of caspase 8 in the early steps of lymphocyte activation.

HLA class II expression deficiencies

These are a rare primary immunodeficiency with autosomal recessive inheritance characterized by defective expression of the HLA-II molecules. It is associated with a severe immunodeficiency. About 100 cases have been reported so far. Infection onset occurs within the first years of life, usually with recurrent pulmonary infections and chronic diarrhea. Chronic cholangitis caused by cryptosporidia is a frequent complication. Viral meningoencephalitis can also occur. Various autoimmune manifestations can be associated. The immunological phenotype is characterized by a CD4 T lymphocytopenia, defective, antigen-specific, HLA-II-restricted, T-cell responses, and defective antibody production (Klein et al. 1993). Detectable CD4 T cells are thought to be the consequence of residual HLA-II expression by thymic epithelial cells. The disease is genetically heterogeneous and four complementation groups have been described. Corresponding genes have been cloned. Their products are all involved in the transcriptional control of HLA-II genes. In group A, a class II transactivator (CIITA), a protein inducible by IFNγ, is defective. It acts as a master control of the binding of proteins to the promoter (Steimle et al. 1993). In groups B, C, and D, respectively, RFX-ANK/RFX-B, RFX5, and RFX-AP were found to be the deficient factors. They are all transcription factors binding to the so-called X box present in HLA-II gene promoters (Steimle et al. 1995; Durand et al. 1997; Masternak et al. 1998; Nagarajan et al. 1999). HLA-II expression cannot occur in the absence of one of them. A variant of the disease with a milder deficiency was recently shown to be a group B variant (Nekrep et al. 2002). There are, however, some variations in phenotype because milder clinical and immunological expressions were described in a small number of kindreds without clear evidence of a leakiness of HLA-II expression (Wiszniewski et al. 2001). HLA-II expression deficiency is instrumental in demonstrating the in vivo central role of CD4 T cells in the generation of efficient immune responses in humans (Villard et al. 2001).

TAP deficiencies

About 10 cases of either TAP-1 or TAP-2 deficiencies have been reported (de la Salle et al. 1994, 1998). TAP-1/TAP-2 make up the HLA-I-associated peptide transporter that goes from the cytosol into the endoplasmic reticulum. Their deficiencies lead to reduced HLA-I expression, inconstantly associated with CD8 T and NK cell lymphopenia.

Clinical consequences are rather unexpected and consist of chronic bronchopneumonitis and in some patients severe vasculitis possibly caused by NK cell aggression to endothelial cells that weakly express HLA-I (Moins-Teisserenc et al. 1999). No clear susceptibility to viral infections has been shown.

Immunodeficiencies with genomic instability

A number of primary immunodeficiencies have been found to be associated with lymphocytic cytogenetic abnormalities, which were later found to correspond to a genomic instability syndrome. They usually provoke a combined T- and B-cell immunodeficiency of increasing severity with age as a result of progressive lymphocytopenia. They are variably associated with a risk of malignancies, particularly lymphomas.

DNA LIGASE 4 DEFICIENCY

DNA ligase 4 deficiency has first been retrospectively found in a child who developed unexpected severe complications of chemotherapy received as treatment for leukemia. It was then found that missense mutations of DNA ligase 4 cause a complex syndrome associating microcephaly, mild learning disability, dysmorphic syndrome, and a combined T- and B-cell immunodeficiency of variable intensity (O'Driscoll et al. 2001). DNA ligase 4 is involved in the ligation of coding ends in the nonhomologous end-joining (NHEJ) process used for V(D)J rearrangements of TCR and B-cell receptor (BCR) genes. It is thus understandable that hypomorphic mutations lead to a partial T- and B-cell immunodeficiency as also found for Artemis deficiency (see above). A case of DNA ligase 1 deficiency has been described in a patient with growth failure, sensitivity to ultraviolet light, severe combined immunodeficiency, and lymphoma (Barnes et al. 1992).

ATAXIA TELANGIECTASIA

Ataxia telangiectasia (AT) is a condition with autosomal recessive inheritance and a 1:40 000 incidence, associating progressive cerebellar ataxia with degeneration

of Purkinje cells, oculocutaneous telangiectasias, and an immunodeficiency. The last, in most cases, consists of severe IgA, IgG2, and IgE deficiencies causing recurrent sinopulmonary infections. A progressive reduction in T-cell counts is also observed, although usually there is no susceptibility to opportunistic infections. A hallmark of the disease is illegitimate recombination of BCR and TCR genes inducing chromosomal translocations or inversions. It is the consequence of a genomic instability syndrome marked by a loss in the cell cycle checkpoints because AT cells exhibit radio-resistant DNA synthesis (Gatti et al. 1991; Shiloh 1997). These patients are at very high risk for lymphomas and also mucosal carcinomas. The AT gene has been cloned by Shiloh's group. The *ATM* gene encodes a 350-kDa protein of the phosphatidylinositol-3-phosphate kinase family (Savitsky et al. 1995). It acts as a sensor of DNA lesions together with the MRE 11/Nbs-1/Rad50 complex (see below) and activates a number of metabolic pathways involved in DNA repair or inducing cell apoptosis (Shiloh and Kastan 2001).

A minority of patients with a similar phenotype (AT-like disorder or ATLD) carries mutations of the *MRE-11* gene, part of a complex with Nbs-1 and Rad-50 involved in DNA break sensing and repair (Stewart et al. 1999).

NIGMEGEN BREAKAGE SYNDROME

Nigmegen breakage syndrome (NBS) shares some common findings with AT, i.e. abnormal chromosomal rearrangements, immunodeficiency (although more severe in NBS), and predisposition to lymphomas (Weemaes et al. 1981). There are, however, neither ataxia nor telangiectasias. In contrast, NBS patients present with microcephaly and learning disability. There is a profound T-cell lymphocytopenia in NBS with very poor survival. The NBS gene encodes nibrin or nbs-1, a member of the MRE-11/Rad-50/NBS-1 complex, which is activated by *ATM*, binds to DNA double-stranded breaks, and is involved in DNA repair (Carney et al. 1998; Varon et al. 1998).

IMMUNODEFICIENCY, CENTROMERIC INSTABILITY, AND FACIAL ANOMALIES

This rare syndrome with autosomal recessive inheritance associates a facial dysmorphic syndrome and an immunodeficiency. The latter varies from mild hypogammaglobulinemia to severe T-cell immunodeficiency with severe chronic diarrhea (Brown et al. 1995). There is a typical cytogenetic feature consisting of multi-branched chromosomal configurations caused by elongation of secondary constrictions. This abnormality results from defective DNA methylation caused by recessive mutations of the DNA methyl transferase *DNMT3B* gene (Ellis et al. 1995; Xu et al. 1999). The relationship between DNA methylation and immunodeficiency is presently unclear.

BLOOM SYNDROME

This is a rare entity characterized by short stature, light-induced skin lesions, and predisposition to cancer. An immunodeficiency, mostly hypogammaglobulinemia, is often found. This condition is caused by deficiency in the Bloom mutant BLM, a DNA helicase (Xu et al. 1999).

Immunodeficiency with bone abnormalities

Short limb dwarfism or cartilage hair hypoplasia (CHH) is an autosomal recessive disorder associating a short stature with metaphyseal chondrodysplasia, hypoplastic hair, and a T-cell immunodeficiency. This condition is rare and has been mostly described in Finnish and Amish populations, although cases have been found worldwide. The T-cell immunodeficiency varies from a severe T lymphopenia with predispositions to classic infections to a mild, almost asymptomatic immunodeficiency (Makitie and Kaitila 1993). Associated features such as erythroblastopenia, cancer, and Hirschsprung's disease are not uncommon. The CHH-related gene has been recently identified. It encodes an untranslated RNA molecule, which forms part of an RNase ribonuclease mitochondrial RNA processing gene (RMRP) gene complex with endoribonuclease activity. Multiple mutations have been found (Ridanpaa et al. 2001). The physiopathology so far remains obscure.

A severe T-cell immunodeficiency has also been described in association with spondyloepiphyseal dysplasia, nephropathy, cortical blindness, and pigmentary skin changes. This very rare 'Schimke immuno-osseous dysplasia' has recently been shown to be caused by mutations of the *Smarcal* gene (Boerkoel et al. 2002).

Wiskott–Aldrich syndrome

Wiskott–Aldrich syndrome (WAS) is a well-known X-linked inherited condition characterized by the association of a complex immunodeficiency with a bleeding disorder and eczema (Ochs and Rosen 1998). Its incidence is around 1:250 000 live births. There is a spectrum of severity of the disease from isolated thrombocytopenia to a severe immunodeficiency with autoimmune manifestations, which include diffuse vasculitis (McCluggage et al. 1999) and a risk of lymphomas. Patients are prone to infections by encapsulated bacteria, essentially because IgM production is reduced. There is also a susceptibility to viral infections (herpes group particularly) possibly because of a gradual loss in T lymphocytes with age (Ochs and Rosen 1998). The *WASP* gene encodes the *WASP* protein, which is expressed by hemopoietic cells (Derry et al. 1994). *WASP* has multiple interaction sites for protein–protein interactions. In T lymphocytes, *WASP* is involved in rearrangement of the actin cytoskeleton on activation.

WASP-deficient lymphocytes lack surface microvilli and do not normally form filopodal and lamellipodal extensions (Remold-O'Donnell et al. 1996). Polarization of TCR-activated T cells is abnormal (Dupre et al. 2002). It is likely that *WASP* defects impair complex processes involved in activation, migration (in particular response to chemokines), and possibly survival of lymphocytes. There is apparently some degree of correlation between *WASP* genotypes and severity of the phenotypes (Ochs and Rosen 1998). Of note, female cases with WAS have been described in relation either to an abnormal X-chromosome inactivation pattern (predominant inactivation of the X chromosome carrying a normal *WASP* allele) (Parolini et al. 1998) or possibly to an unrelated disease.

Hyper-IgM syndrome: conditions predisposing to opportunistic infections

A 'classic' form of B-cell immunodeficiency is characterized by defective immunoglobulin class switch recombination (CSR) resulting in normal to high levels of serum IgM with very low production of IgG, IgA, and IgE. It is termed the hyper-IgM syndrome (HIgM). Genetic and clinical heterogeneities were noticed a long time ago because there are both X-linked and autosomal recessive forms of HIgM and some patients are prone to opportunistic infections not seen in B-cell immunodeficiencies. These observations led to a progressive delineation of very distinct conditions within the HIgM entity. In this section, only HIgM conditions leading to opportunistic infections are described.

X-LINKED HIGM-CD40L DEFICIENCY

B lymphocytes from X-linked HIgM patients can be induced to switch in vitro to the production of the different Ig isotypes, provided appropriate stimuli are present. This X-linked condition is caused by mutations of the gene encoding the CD40 ligand (CD40L) protein (Notarangelo and Hayward 2000). The latter is expressed at the surface of activated T cells; it is a member of the TNF family. By interacting with CD40 at the B-cell surface, CD40L delivers an essential (but not sufficient) signal for inducing Ig CSR and germinal center formation. However, several patients with CD40L deficiency not only are at risk for bacterial infections of the respiratory tract, as observed in other B-cell immunodeficiencies (see below), but also develop infections related to other mechanisms (Levy et al. 1997). Infected oral ulcerations can be a consequence of neutropenia, frequently found during the course of an infection and probably explained by a CD40-mediated, stress-induced granulopoiesis. More striking is the high risk of CD40L-deficient patients developing infections caused by pathogens that can invaginate in the membrane of epithelial cells, i.e. *P. carinii* and *Cryptosporidium parvum*, causing respectively interstitial pneumonitis and chronic diarrhea. In addition, chronic infections by *Toxoplasma gondii* have been reported. These infections are life-threatening in this setting, e.g. chronic *C. parvum* infection can lead to cholangitis and eventually liver cirrhosis caused by chronic inefficient TNF-mediated inflammation (Ponnuraj and Hayward 2002). These observations stress the role of CD40L in immunity to such pathogens. Mechanism(s) by which CD40L mediates effector functions is not precisely known. It has been shown in mice that CD40-expressing cells of hemopoietic origin are required for efficient immunity to *C. parvum* (Hayward et al. 2001). It could be that CD40L on activated T cells triggers cytokine production, such as IL-12, by CD40-expressing macrophages and/or that CD40-expressing cells trigger an unknown T-cell function. The former mechanism cannot be considered as sufficient because IL-12-deficient patients have a different spectrum of predisposition to infections (see above).

CD40 DEFICIENCY

A small number of patients with autosomal recessive HIgM exhibit a similar spectrum of infections as a consequence of recessive mutations of the CD40 gene, impairing its expression at the surface of B and other cells (Ferrari et al. 2001).

Deficiencies of the perforin-dependent cytolytic pathway

The study of the so-called hemophagocytic syndrome (HPS), which can be a genetically determined condition, has led to the understanding that impairment of the T- and NK cell cytolytic pathway carries rather unexpected consequences. HPS is characterized by polyvisceral infiltration by activated polyclonal T lymphocytes, mostly CD8, associated with macrophage activation (with hemophagocytosis) and massive release of proinflammatory cytokines (IFNγ, IL-1, IL-6, TNFα) (Henter et al. 1991; de Saint Basile and Fischer 2001). HPS occurrence is usually driven by an infection, very frequently by a herpes group infection, among which Epstein–Barr virus plays an important role. There are four known genetic conditions that can induce this HPS. Three of these conditions clearly share an identical immunological phenotype, i.e. defective T and NK cytotoxic activities. These are familial hemophagocytic lymphohistiocytosis (FHL) caused by perforin deficiency (Stepp et al. 1999), Chédiak–Higashi syndrome (CHS) caused by deficiency in the cytolytic lyst protein (Barbosa et al. 1996), and Griscelli's syndrome caused by a deficiency in the small G protein Rab27a (Menasche et al. 2000).

In the first condition, a major cytolytic component – perforin – is missing. In the next two, the intracellular transport of lysosomal secretory granules is defective

leading to impaired exocytosis of cytolytic granules (Stinchcombe et al. 2001). It is striking to note that cytolytic T-/NK cell deficiency is not primarily a condition of high susceptibility to viral infections (as severe T-cell deficiencies are) but rather a disease of faulty contraction of expanded CD8 T cells after antigen stimulation (viral infection). This is a similar picture to the one observed in otherwise phenotype-free perforin$^{-/-}$ mice, once infected with the lymphocytic choriomeningitis virus (Matloubian et al. 1999).

A fourth condition is inherited with an X-linked pattern – X-linked proliferative syndrome (XLP) or Purtilo's syndrome. Affected males can develop a similar HPS syndrome usually once infected by Epstein–Barr virus (EBV), although some others can develop lymphomas and/or hypogammaglobulinemia (Morra et al. 2001). XLP is the consequence of mutations of the *SAP/SH2DIA* gene, which is expressed by T and NK cells and is involved in signaling by membrane molecules of the SLAM family (SLAM and 2B4 particularly) (Latour et al. 2001). SLAM–SLAM homologous interaction, and possibly 2B4 interaction with CD48 at the surface of EBV-infected B cells triggers fyn tyrosine kinase activation (Morra et al. 2001). It is unclear yet what the roles of these signaling pathways are. They have been shown to control T-helper 2 T-cell immune response. Interestingly, in the absence of SLAM-associated protein (SAP), the 2B4 NK cell co-receptor triggers inhibitory signals for cytotoxicity (Parolini et al. 1998). It is thus plausible that HPS as observed in XLP usually driven by an EBV infection is also the consequence of defective cytotoxic T lymphocyte (CTL)/NK cytolytic activity. Much remains to be done to understand its mechanism fully. Of note, there are more genetically determined HPS conditions that have not yet been molecularly characterized.

Other T-cell immunodeficiencies

CHRONIC MUCOCUTANEOUS CANDIDIASIS

Some patients exhibit an exquisite sensitivity to infections by candida species. This condition is known as chronic mucocutaneous candidiasis (Kirkpatrick 1994; Lilic 2002). It can persist as a strictly specific predisposition to candida infections of nails, skin, and mucosae associated with a specific deficiency in T-cell response to *Candida*, or become associated later in life with variable Ig isotype deficiencies. Several patterns of inheritance have been described. Cerebral aneurysms can complicate this condition, possibly as a consequence of a vascular fungal infection (Loeys et al. 1999). A locus has been mapped to chromosome 2 (Atkinson et al. 2001), but so far there is no hint about the molecular mechanism underlying this unique infection predisposition. In some cases, chronic candida infection is associated with autoimmune manifestations particularly targeting endocrine glands. This syndrome is known as autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy (APECED) Ahonen et al., 1990; Finnish–German APECED Consortium 1997). This rare condition is caused by mutations of the gene encoding the AIRE protein, a transcription factor expressed by thymic medullary epithelial cells (TEC) (Nagamine et al. 1997). It has been recently shown that in AIRE$^{-/-}$ mice, which also exhibit autoimmune polyendocrinopathy, AIRE-deficient TEC cells do not express proteins from mature organs, thus preventing a negative selection of autoimmune T-cell clones (Anderson et al. 2002). This work does not, however, provide an explanation on the mechanism of susceptibility to candida infections.

IDIOPATHIC CD4 LYMPHOCYTOPENIA

This condition resembles AIDS, because it is marked by a profound (<300/mm^3) CD4 T-cell lymphocytopenia, but is not caused by HIV, or by any other known environmental trigger (Smith et al. 1993). Opportunistic infections occur as a consequence of this syndrome frequently associated with inflammatory or autoimmune diseases. No etiology is known. The mechanism of CD4 T-cell lymphocytopenia (premature apoptosis?) remains elusive.

B lymphocytes

Genetic disorders of B lymphocytes predominate by far, because they represent 70 percent of primary immunodeficiency disorders (Figure 5). Bruton (1952) made the very first description of an immunodeficiency in 1952, X-linked agammaglobulinemia. Since then, several syndromes have been described and, accordingly, the role of the different Ig isotypes in infectious immunity has been better understood. Still, the molecular mechanism of the most frequent form(s) of B-cell immunodeficiency, i.e. common variable immunodeficiency and IgA deficiency, remains elusive (see below).

AGAMMAGLOBULINEMIA

Prototypic B-cell immunodeficiency consists of genetic defects impairing B-cell development. Four such conditions have been described leading to the autosomal recessive form of agammaglobulinemia (Gaspar and Conley 2000). An early block in B-cell development results in a complete absence of mature B cells and thus of Ig production whereas the other cells of the immune system are spared. They thus do provide a 'pure' model to study consequences in humans of an absence of B-cell-mediated immunity. Onset of infections occurs in the first year of life after a few months' delay because of the transient protection provided by maternally transmitted IgG. The most frequent sites of infection are the upper respiratory tract, the lower respiratory tract, the

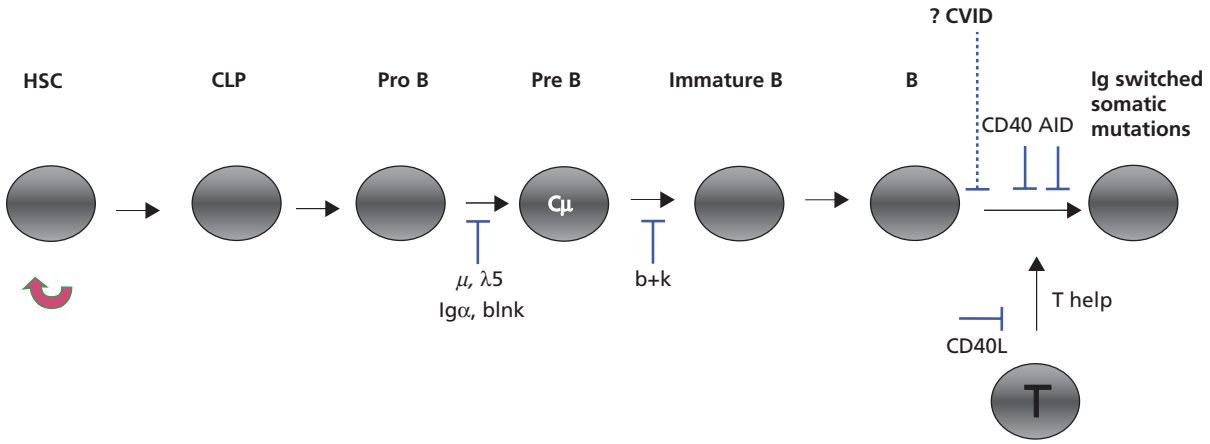

Figure 5 *B-cell immunodeficiencies. HSCs (hemopoietic stem cells) differentiate into putative CLPs (common lymphocyte progenitors), giving rise among other lineages to the B-lymphocyte lineage. There is a block in B-cell development (see text for explanation). CVID, common variable immunodeficiency.*

gut, the skin joints, the eyes, and the central nervous system, and sepsis also occurs (Smith and Witte 1998).

Upper and lower respiratory tract infections are recurrent, progressively leading to chronic infectious lesions of the sinuses and bronchi. Bronchiectasis develops which can lead in the absence of treatment to pulmonary insufficiency (Quartier et al. 1999; Conley and Howard 2002; Lopez Granados et al. 2002). The most frequently encountered microorganisms are *H. influenzae*, *S. pneumoniae*, gram-negative bacilli such as *Pseudomonas aeruginosa*, i.e. encapsulated bacteria. In the gut, *Giardia lamblia* causing a chronic parasitic infection can occur. Chronic mycoplasma infections of the joints have also been described. Agammaglobulinemic patients are not prone to viral infections with a single important exception. Chronic enteroviral infections are indeed not uncommon in this setting. Live attenuated polioviruses can induce a severe chronic neurological disease. Chronic enteroviral infections have a large spectrum of expression from chronic diarrhea, failure to thrive, arthritis, hepatitis, pseudo-dermatomyositis osteomyeolitis, to more commonly meningoencephalitis (Quartier et al. 1999; Conley and Howard 2002; Lopez Granados et al. 2002). It remains by far the most severe infectious complication in B-cell-deficient patients. Enteroviral infection can occur in an otherwise well-treated patient. It is difficult to control. It is still unknown how agammaglobulinemic patients exhibit such a high susceptibility to enteroviral infections despite the normality of their T-cell compartments. Some specificity of enterovirus–host interaction remains obviously unknown.

It is interesting to note that IgG substitution by intravenous or subcutaneous route is highly efficient in preventing most of bacterial infections (unless bronchiectasis or a chronic sinusitis is present) suggesting that IgG can essentially substitute the IgA function at mucosal surfaces. Although it is unclear how IgG diffuses at mucosal surface, this observation may help to understand that many IgA-deficient patients are not particularly susceptible to infections.

AUTOSOMAL RECESSIVE AGAMMMAGLOBULINEMIA

There are four conditions characterized by a complete absence of mature B cells because of a block in B-cell differentiation at the pro-B-cell level (Yel et al. 1996; Minegishi et al. 1998, 1999a, 1999b). Mutations in the μ heavy chain gene, the λ5 surrogate light chain gene, the Igα, or the BLNK genes all result in the same phenotype. The faulty expression of a pre-B-cell receptor (Ig μ heavy chain/surrogate light chain) or of the associated signaling apparatus (Igα/CD89a or blnk) prevents further progression in the B-cell development pathway. These are rare conditions, but other autosomal recessive inherited agammaglobulinemias have not yet reached molecular understanding.

X-LINKED AGAMMAGLOBULINEMIA (BRUTON'S DISEASE)

X-linked agammaglobulinemia (XLA) accounts for about 80 percent of the cases of 'agammaglobulinemia'. It is caused by mutations of the Bruton tyrosine kinase gene (*btk*) (Vetrie et al. 1993; Tsukada et al. 1993). However, in most cases, B-cell development block is not as complete as it is in autosomal recessive agammaglobulinemia. Patients tend to have low but variably detectable serum concentrations of the different Ig isotypes. Peripheral B cells can in some cases be detected in the periphery. Typically, bone marrow B-cell differentiation is blocked at the pre-B-cell level (B cells expressing the μ/pseudo light chain complex at the surface). Therefore, the clinical consequence, although very similar to those of autosomal recessive agammaglobulinemia, tends to have a slightly later onset and be slightly less severe (Lopez Granados et al. 2002).

Phenotypic variability is unexpectedly high because several patients with *btk* mutations exhibit a phenotypic picture reminiscent of common variable immunodeficiency (CVID) (see below), i.e. B cells are detectable in periphery (up to 5 percent lymphocytes) with serum IgG concentration up to 2–3 g/l. This variability is independent of the genotype as observed within affected kindreds (Smith and Witte 1998). The extreme of the spectrum has been described as a pure deficiency in antibody response to polysaccharide antigens (Wood et al. 2001). This is actually reminiscent of the *btk*-deficient murine model, either natural (CBA/N-XID strain) or obtained by *btk* gene inactivation, which essentially exhibits a defect in antibody response toward type 2 T-independent antigens (Rawlings et al. 1993). It is possible that modifier genes (with or without environmental factors) modulate the phenotypic expression of XLA.

The btk kinase belongs to the Itk/Tec tyrosine kinase family. It is expressed by hemopoietic cells but seems essential in B-cell and possibly mastocyte development/function. Mutations affecting essentially all domains of the molecules (PH, TH, SH_3, SH_2, and kinase) have been described; *btk* appears as an essential component for signal transduction from several B-cell receptors (BCR) including surface Ig (antigen-specific BCRs), CD40, and cytokine receptors for IL-5, -6 and -10 (Smith and Witte 1998). Calcium flux after phospholipase C γ (PLCγ) phosphorylation, an essential event in BCR-triggered B-cell activation, is dependent on *btk* integrity.

HYPER-IGM SYNDROMES

As described above, HIgM syndromes are the in vivo consequences of defective Ig class switch recombinant (CSR). Besides CD40L–CD40 deficiencies, there are pure HIgM B-cell immunodeficiency conditions. Defective IgG and IgA production is associated with typical susceptibility to bacterial infections in the respiratory and gastrointestinal tracts (Conley et al. 1994). This is most often accompanied by lymph node enlargement as a consequence of hypertrophic germinal centers, full of proliferating B cells. Further phenotypic characterization of this syndrome has revealed that there is also a defect in IgV region somatic hypermutations (SHM). This condition, called HIgM2 syndrome, has been ascribed to activation-induced deaminase (AID) gene recessive mutations (Revy et al. 2000). AID is selectively expressed in germinal centers. It belongs to an RNA-editing enzyme family. AID is thus necessary for both events of somatic Ig gene rearrangements and somatic mutations required for antigen-driven antibody maturation. It is still not known whether AID indeed edits mARN-encoding protein(s) involved in CSR and SHMs or directly modifies DNA as recently suggested (Petersen-Mahrt et al. 2002). There are still HIgM syndromes that are not accounted for by AID gene mutations. Their study might contribute to a further description of the molecular pathways involved in CSR and SHMs.

COMMON VARIABLE IMMUNODEFICIENCY AND IGA DEFICIENCY

IgA deficiency is the most common form of primary immunodeficiencies but it is frequently an asymptomatic condition. Common variable immunodeficiency (CVID) occurs in 1:25 000 individuals, with onset of symptoms usually during the second or the third decade of life (Hammarstrom et al. 2000). It is characterized by a variably decreased concentration of all Ig isotypes. Patients with CVID and symptomatic IgA deficiency are prone to infections similar to the ones encountered in agammaglobulinemic patients. In addition, however, these patients, during adulthood, become at risk of developing granulomatous lesions, inflammatory bowel disease, autoimmune diseases, and cancer. Inheritance pattern of CVID and IgA deficiency is not entirely clear but it is often compatible with an autosomal dominant pattern with variable penetrance. Both conditions can be found in the same kindred or subsequently in the same individual, suggesting that these two conditions are allelic.

Despite intensive research, there is still very little known about the physiopathology of CVID and IgA deficiency. B-cell counts in blood can be diminished (with a trend to decline). There are variable B-cell phenotype abnormalities, which have led to CVID subclassification (Warnatz et al. 2002). It is not known, however, whether this corresponds to potentially distinct disease mechanisms. In some of the patients, functional T-cell defects have also been observed. It is also not known whether there are primary or secondary T-cell abnormalities. Patients with IgA deficiency very often have anti-IgA antibodies. It has been suggested that anti-IgA antibodies could play a causative role because women transmitting the disease have a higher prevalence of anti-IgA antibodies that could induce IgA deficiencies in offspring (Vorechovsky et al. 1999, 2000). Genetic linkage between CVID and IgA deficiency and the HLA locus has been demonstrated. There is a debate about whether the HLA-III region (between the C4b and the C2 genes) and/or the HLA-II region (HLA-DQ locus) is involved (Schroeder et al. 1998; Vorechovsky et al. 1999).

Of note, drug-induced Ig deficiencies (IgA deficiency or CVID) have been described without known mechanisms. IgA deficiency has been also described in patients with aberrations of chromosome 18.

IGG ISOTYPES DEFICIENCIES

Variable IgG isotypes deficiencies have been reported, as either, very rarely, the consequence of autosomal recessive deletions of IgH genes (IgG1 deficiency) or selective IgG2 and -4 (often with IgA) deficiency

without abnormality of IgH genes (Oxelius et al. 1981). In the last case, there is a selective antibody production deficiency toward the polysaccharide wall of *S. pneumoniae*, *H. influenzae*, and *P. aeruginosa*, which make these patients very susceptible to infections by these bacteria. The relationship between the γ2 gene and specificity of IgG2 antibodies remains puzzling. The physiopathology is unknown. There are family cases suggestive of autosomal recessive inheritance.

Selective antibody production deficiency to polysaccharides without diminution in serum Ig isotypes levels has also been described in a few cases. It has been proposed that such deficiency could reflect a defect in T-independent B1 cell function, but this remains highly hypothetical.

Acquired immunodeficiencies

RALF IGNATIUS AND THOMAS SCHNEIDER

Introduction	1	Measles	17
HIV infection	3	References	20
HTLV-1 infection	15		

INTRODUCTION

Acquired immunodeficiency represents an emerging medical challenge, the major medical causes of which are summarized in Table 1. In contrast to primary immune deficiencies, which are rare and at constant numbers over the last decades, the numbers of patients with acquired immunodeficiency are dramatically increasing. This is the result not only of the pandemic spread of the human immunodeficiency virus (HIV) (Clinton 2003) but also of rising numbers of patients on immunosuppressive therapy or who have diabetes, leukemia, Hodgkin's disease, or rheumatic disorders, or who are alcohol abusers (Murray and Lopez 1997; Singer and McCune 1999; Mossad et al. 2001; Simon and Fleischhack 2001; Messingham et al. 2002). In addition, older age is a well-known condition of acquired immunodeficiency (immunosenescence), and the numbers of older individuals have been continuously increasing in developed countries (Gavazzi and Krause 2002). In some regions of the world, e.g. Australia, the increasing ultraviolet radiation may also exert immunosuppressive effects (Staples et al. 2003).

Importantly, malnutrition of children in developing countries is still an unsolved problem, leading in these children to immunodeficiency, which considerably increases their susceptibility to the leading infectious causes of death world wide: enteric and pulmonary infections (reviewed by Bhaskaram 2002). It may come as a surprise to many that malnutrition in childhood is less often the result of lack of food than of the enormous burden of infectious diseases, notably diarrheal diseases, that commonly afflicts children in the developing world. Infective diarrhea reduces food intake and increases the loss of important nutrients from the body. After a single infection the child can recover rapidly and may suffer from only a brief period of accelerated height and weight velocity called 'catch-up' growth. In the developing world, however, repetitive episodes of diarrhea are often seen in children, thus greatly impairing their chances of regaining lost growth. The accumulative effect of such episodes greatly influences the growth and mental development of these children, and at the same time also has a profound impact on their immunological defense mechanisms (reviewed by Keusch 1982, 2003).

In addition to the aforementioned causes for acquired immunodeficiency, phases of immunosuppression may also occur in the context of various infectious diseases. Infections with HIV, human T-cell lymphotropic virus 1 (HTLV-1), and measles virus all induce suppression of cellular immune responses, leading to clinically apparent secondary infections and/or tumors. These diseases are of varying epidemiological importance. The horrendous spread of the HIV-1 pandemic is well recognized and the World Health Organization (WHO) has estimated that there were 40 million infections worldwide at the end of 2001, whereas HTLV-1 infection possesses rather regional interest. Sadly, despite the opportunity to prevent measles through effective immunization, about 1.1 million children died in 1990, mostly in developing countries, from measles-related events (Murray and Lopez 1997), and in 1999 the number of deaths caused by measles was estimated as 700 000 (Duke and Mgone 2003). In most cases, secondary infections, such as bacterial pneumonia, often combined with malnutrition, but not measles itself, were the cause of death (reviewed in Schneider-Schaulies and ter Meulen 2002).

Table 1 *Causes of acquired immunodeficiency*

Disease	Suspected immune defect	Frequent infectious diseases
Infection		
HIV	Loss of $CD4^+$ T cells, MHC I downregulation	PCP, toxoplasmosis, CMV infections, microsporidiosis, and others
HTLV-1	Impaired T- and B-cell function	Strongyloidiasis, cryptococcal meningitis, PCP
Measles	Transient lymphopenia, transient reduced Th1 response	Bacterial pneumonia, otitis media, sinusitis
Neoplasms		
Hodgkin's disease	Impaired T-cell function	Infections with intracellular bacteria: TBC, listeriosis, salmonellosis
Multiple myeloma	Hypogammaglobulinemia	Bacterial pneumonia and meningitis
Chronic lymphocytic leukemia	Hypogammaglobulinemia	Bacterial pneumonia and meningitis
Acute myelocytic or lymphocytic leukemia	Granulocytopenia	Infections with extracellular gram-positive and gram-negative bacteria, fungal infections
Other conditions		
Diabetes	Impaired cell-mediated immunity and phagocyte function	Fungal infections (candidiasis, mucormycosis), urinary tract and soft tissue infections
Alcoholism	Impaired cell-mediated immunity and phagocyte function	TBC, soft tissue infections, osteomyelitis
Old age (elderly)	Impaired T- and B-cell function	Bacterial pneumonia, TBC, urinary tract and soft tissue infections, viral diarrhea, *Clostridium difficile* toxin-induced colitis
Splenectomy[a]	Reduced immune response against bacteria	Bacterial pneumonia, bacterial meningitis, babesiosis
Iatrogen (therapy-induced immune suppression)		
Drugs frequently used in autoimmune diseases		
Glucocorticoids	Impaired monocyte and T-cell activation	Fungal infection, bacterial pneumonia
Cyclophosphamide[b]	Reduces antigen driven T- and B-cell response	Bacterial and fungal infection, PCP, CMV infections
Methotrexate[b]	Inhibition of antibody production, lymphopenia, monocytopenia	Bacterial and fungal infection, PCP, CMV infections
Anti-TNF-α[c]	Suppression of inflammatory response, reduces granulocyte and macrophage activation	Reactivation of TBC, bacterial and fungal infections
Drugs frequently used in organ transplant recipients		
Ciclosporine, FK-506 (tacrolimus), rapamycin	Inhibition of T-cell activation (inhibition of IL-2 gene activation)	Reactivated viral infections (especially herpesvirus group), infections with respiratory syncytial virus, adenovirus, and parvovirus B19
Azathioprine	Inhibition of antibody production, lymphopenia, monocytopenia	Bacterial and fungal infections
Anti-CD3, anti-CD4, anti-IL2	Inhibition of T-cell activation	PCP, reactivated viral infections (especially herpesvirus group), infections with respiratory syncytial virus, adenovirus, and parvovirus B19
Drugs and methods frequently used in tumor therapy		
Cytostatic therapy	Reducing the number of B cells, T cells, macrophages, and granulocytes	CMV infections, progressive multifocal leukencephalitis (JC virus infection), PCP
Radiation	Suppression of number and function of T and B cells	CMV infections, progressive multifocal leukencephalitis (JC virus infection), PCP

CMV, cytomegalovirus; IL, interleukin; MHC, major histocompatibility complex; PCP, *Pneumocystis carinii* pneumonia; TBC, tuberculosis; TNF, tumor necrosis factor.

a) If splenectomy can be planned patients should receive haemophilus, meningococcal, and pneumococcal immunization before.

b) Patients who are treated with this immunosuppressive drug (either cyclophosphamide or methotrexate) in combination with glucocorticoids should receive trimethoprim–sulfamethoxazole as prophylaxis against PCP.

c) Patients with positive tuberculin test or TBC in their history treated with anti- TNF-α should receive isoniazid as prophylaxis against TBC reactivation.

The scope of this chapter is to concentrate on these three viral infections which have various similarities but also significant differences with respect to their effects on cellular immune functions. Importantly, HIV and HTLV-1 are retroviruses and integrate via a provirus in the human genome; thereby they can persist and potentially cause life-long damage to the immune system. In contrast, effective immune responses are usually induced against measles virus; these lead to viral clearance, and immunosuppression lasts for only a limited period of time.

HIV INFECTION

The virus

In 1983 scientists from the Pasteur Institute in Paris recovered the causal agent of acquired immune deficiency syndrome (AIDS) from lymph nodes of an asymptomatic individual with generalized lymphadenopathy (Barré-Sinoussi et al. 1983). This new retrovirus was finally named HIV-1. HIV-1 belongs to the lentiviruses in the taxonomic classification of retroviruses (Gelderblom et al. 1985). The lentiviruses are complex spherical viruses characterized by a unique virion morphology with cylindrical or conical cores (Gelderblom et al. 1987). The proviral genome of HIV-1 encodes *gag*, *pol*, and *env* genes characteristic of all known retroviruses. Both ends of the proviral genome are flanked by noncoding direct-repeat sequences called long terminal repeats (LTR). LTRs mediate proviral integration and contain *cis*-acting regulatory elements important for viral transcription, viral mRNA processing, and reverse transcription. The LTRs of HIV-1 also contain the binding site for NF-κB, which is present in the nuclei of activated human T lymphocytes and can stimulate both basal and Tat-induced levels of HIV-1 replication (Nabel and Baltimore 1987). The genome structure of human pathogenic retroviruses is more complex than that of other retroviruses, containing several additional open reading frames encoding for nonstructural regulatory or accessory proteins. Some of these viral proteins may contribute to immunosuppression.

Tat is an indispensable viral protein, which increases the steady-state levels of viral RNA by a multiplication factor of around several hundred (Dayton et al. 1986). Tat seems to be involved in T-cell activation that results in an increased viral transcription in two ways: increasing the concentration of cellular factors CDK9 and cyclin T1 for Tat activation and increasing the activation of NF-κB. Tat may also inhibit antigen-induced, but not mitogen-induced, proliferation of peripheral blood mononuclear cells (PBMC) and therefore play a role in immunosuppression (Viscidi et al. 1989).

Nef seems to have a positive influence on the progression to AIDS in vivo (Kestler et al. 1991). It may ensure survival of HIV-1 through distinct mechanisms of immune evasion and antiapoptosis (for a review, see Fackler and Baur 2002). In vitro, several functions of Nef have been described:

- Nef downregulates the cell surface expression of CD4 (Garcia and Miller 1991). Studies with HIV-Nef mutants in severe combined immunodeficiency (SCID) mice implanted with human fetal thymus revealed that the functional domain that is required for CD4 downregulation correlates with Nef-mediated enhancement of viral pathogenesis (Stoddart et al. 2003). The ability of Nef to downregulate CD4 may influence the function of T-helper cells and contribute to acquired immunosuppression of HIV-infected patients.
- Nef downregulates the cell surface expression of major histocompatibility complex (MHC) class I molecules (Schwartz et al. 1996). This MHC I downregulation may limit the ability of cytotoxic T lymphocytes (CTL) to recognize and eliminate HIV-infected cells and may be one way that the virus escapes the host's immune response (Collins et al. 1998). More sophisticated Nef selectively downregulates certain MHC I molecules, avoiding downregulation of those (HLA-C and HLA-E), that would induce attack by natural killer (NK) cells (Cohen et al. 1999).
- One important function of Nef may be the activation of lymphocytes (Luo and Peterlin 1997). A natural occurring mutant simian immunodeficiency virus (SIV) nef allele induces extensive T-cell activation and proliferation (Du et al. 1995). This mutant is only an arginine-to-tyrosine mutation in the *nef* gene, which results in a sequence reminiscent of an immunoreceptor tyrosine-based activation motif (ITAM). Such motifs in the cytoplasmic tails of T- and B-cell receptors are essential for lymphocyte activation. The SIV *nef* mutant seems to activate T-cell signaling (Luo and Peterlin 1997). Macaques infected with this SIV strain rapidly develop a fatal disease, leading to the death of the animals because of severe gastrointestinal symptoms (Du et al. 1995). Nef expression in macrophages induces expression and secretion of the chemokines macrophage inflammatory protein (MIP) MIP-1α and MIP-1β, which are capable of activating lymphocytes (Swingler et al. 1999).

Natural course of HIV infection

The course of HIV-1 infection is usually divided into three phases: (1) the primary HIV-1 infection, (2) the chronic asymptomatic phase and (3) AIDS; the individual pattern and course of the disease may, however, be highly variable.

THE PRIMARY HIV-1 INFECTION

Primary HIV-1 infection (PHI) is rarely diagnosed and represents a self-limited disease. However, recognition

of this early phase of HIV-1 infection is important for two major reasons. First, the severity of PHI predicts progression to AIDS; it is therefore thought that treatment of PHI may prevent or retard progression to AIDS. Second, from the public health perspective the diagnosis of PHI is important because these patients are highly infectious and early diagnosis will prevent the spread of disease to the patients' sexual partners. The severity of symptoms during PHI is highly variable; about 12 percent of seroconverting patients are hospitalized (for a review, see Apoola et al. 2002).

At the beginning of PHI, patients are usually seronegative for anti-HIV antibodies; the p24 antigen-capture assay and polymerase chain reaction (PCR) for the HIV genome are positive. Viremia levels reach extremely high values, and high titers of infectious virus can be isolated from the blood. During the first 5–10 days of PHI, the patients show a characteristic lymphopenia which affects both $CD4^+$ and $CD8^+$ T cells. In this phase, $CD4^+$ T cells may drop to levels as low as those observed in AIDS, and in vitro tests of both B and T cells show impairment. Nevertheless opportunistic infections in this short period are rare (for a review, see Apoola et al. 2002).

During PHI the virus spreads to several organs of the body including the lymph nodes, central nervous system, skin, and mucosa. Therefore, patients with PHI may present variable symptoms. Cutaneous manifestations are frequent and include the classic maculopapular rash or ulcers, which may occur at genital, oral, and esophageal mucosae (Cooper et al. 1985; Schacker et al. 1996). Ulcerations in other parts of the gastrointestinal mucosa are more rarely observed. A common feature of PHI is the so-called 'mononucleosis-like illness', which is characterized by fever, pharyngitis, arthralgia, myalgia, and lymphadenopathy (for a review, see Apoola et al. 2002).

THE CHRONIC ASYMPTOMATIC PHASE

The primary HIV-1 infection is followed by a long-lasting phase of clinical latency of about 8–12 years with a median time of 9.8 years (Bacchetti and Moss 1989). However, 10–20 percent of HIV-infected individuals progress more rapidly to the final stage of the disease in about 5 years (Phair et al. 1992). This group is called 'rapid progressors'. At the other extreme, 5–15 percent of HIV-infected people, called 'slow progressors', will remain in this stage of the disease for about 15 years (Sheppard et al. 1993). This wide variability of the natural course of the disease implicates different driving forces, including genetic factors of the host as well as virological factors (Fauci 1996). In this chronic phase of HIV infection no symptoms are present. Virus replication and $CD4^+$ T cells remain relatively stable during this time. Virus replication and the accumulation of virus trapped by follicular dendritic cells occur in lymph nodes, however, where a progressive structural and functional deterioration takes place, resulting in an impairment of specific immune response over time (Pantaleo et al. 1993). Finally, there is steady decrease of $CD4^+$ T cells with an increasing risk of developing infections (Figure 1). Acquiring an AIDS-defining opportunistic infection leads to the transfer to the end-stage of the disease.

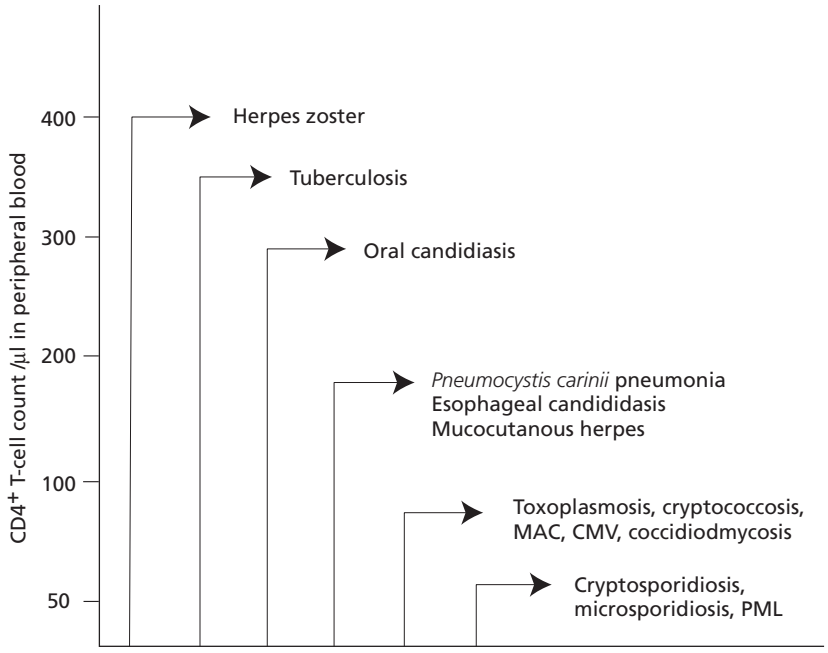

Figure 1 *Association between opportunistic infections and CD4 $^+$ T-cell count.* CMV, *cytomegalovirus; MAC,* Mycobacterium avium complex; *PML, progressive multifocal leukoencephalopathy.*

AIDS

AIDS defines the end-stage of HIV-1 infection. Before the introduction of highly active antiretroviral therapy (HAART), this phase of the disease leads to death within 1–2 years (Bacchetti et al. 1988). The major causes of death are opportunistic infections resulting from a breakdown of the immune system. The hallmark of the disease is a steady decline in the number of $CD4^+$ T cells, which correlates with an increasing number of certain opportunistic infections (Figure 1). Fortunately, the introduction of HAART has significantly decreased morbidity and mortality of HIV-1 infection (Palella et al. 1998).

Immune dysfunctions

$CD4^+$ T LYMPHOCYTES

The progressive loss of peripheral $CD4^+$ T lymphocytes is a hallmark of HIV infection, coinciding with the failure of the immune control toward a variety of infectious pathogens including HIV-1 itself. The underlying mechanisms, however, are still a matter of controversial debate. The increased proliferation and loss of CD4 cells were interpreted as the death of virally infected cells being succeeded by a homeostatic proliferation of new T cells (Ho et al. 1995; Wei et al. 1995). Nevertheless, these conclusions have been questioned based on the observations that (1) relatively small numbers of T cells are actually productively or latently infected in vivo (Haase 1999), (2) significant numbers of uninfected cells apparently die (Finkel et al. 1995), and (3) the decline of CD4 cells in the peripheral blood is not necessarily paralleled by similar changes in the lymphoid tissues (Rosok et al. 1996). As a result, a different scenario was proposed where a general activation of the immune system leads to dysregulated homeostatic processes.

Different T-cell labeling techniques in vivo and mathematical models have been applied to investigate whether the T-cell proliferation is the immunological response to previous T-cell death, or whether cell death is the result of previous activation and proliferation, and T-cell loss is exclusively caused by continuous destruction or additional to impaired production (Douek et al. 2003). The data, however, are inconclusive, indicating complex processes influenced by various host and viral factors, e.g. CD4 T-cell dysfunctions, viral cytopathicity, cytotoxicity, apoptosis, activation-induced cell death (AICD), altered T-cell migration patterns, and impaired T-cell production.

$CD4^+$ T-cell dysfunction

Cytokine production by $CD4^+$ T cells is profoundly perturbed in HIV-1 infection leading to qualitatively and quantitatively different cytokine secretion patterns (see section on Cytokines). In addition, proliferation to alloantigens, e.g. tetanus toxoid and purified protein derivative, and importantly also to HIV antigens is decreased, which is the result of a progressive loss of memory CD4 T cells (Miedema et al. 1988; Clerici et al. 1989; Meyaard et al. 1994). In fact, HIV-specific $CD4^+$ T cells in the peripheral blood are easier to detect by intracellular cytokine staining than by proliferation (Pitcher et al. 1999). The reduced responsiveness of $CD4^+$ T cells in HIV-1 infection correlates with a decreased expression of CD28 and CD40 ligand (Borthwick et al. 1994; Chirmule et al. 1995), as well as changes in the $CD4^+$ T-cell receptor repertoire (Connors et al. 1997; Gea-Banacloche et al. 1998). Notably, patients with long-term non-progressing (LTNP) disease exhibit strong antigen-specific proliferative responses (Rosenberg et al. 1997).

Cytopathicity

HIV-1 preferentially infects rapidly expanding, activated, naïve (HIV-1 specific) CD4 T cells (Douek et al. 2002), and kills the cells by apoptosis independently of the expression of Fas (Gandhi et al. 1998), although necrotic cell death of HIV-1-infected T cells has recently been reported (Lenardo et al. 2002). Additional cytopathic effects involving viral gp120 and CD4 can lead to giant cells (syncytia) that can contain uninfected T cells (Lifson et al. 1986; Sodroski et al. 1986). In vivo this mechanism may be of less importance except for the central nervous system where giant cell formation is more frequently seen in the context of HIV-1 infection (Williams and Hickey 2002). Although viral burden in lymphoid tissue is greater than in peripheral blood where only small numbers of infected cells are usually seen, virus-mediated killing alone most probably does not account for the decline of peripheral CD4 T cells and the development of AIDS.

Cytotoxicity

Death of HIV-infected cells may also be caused by cytotoxic immune responses. There is an early and strong induction of HIV-1-specific CTL responses, and antibody-dependent cellular cytotoxicity (ADCC) may contribute to the reduction of HIV-1 infected cells. Nevertheless, as most of these immune responses are also, at least to some extent, impaired in chronic HIV-1 infection, they most probably do not primarily drive the depletion of $CD4^+$ T cells. Interestingly, lysis of uninfected $CD4^+$ T cells by $\gamma\delta$ T cells has recently been described, thus suggesting a role for this subset in the CD4 T-cell decline in HIV-1 patients (Sindhu et al. 2003).

Apoptosis

In vitro, T cells from HIV-1 infected individuals die of spontaneous apoptosis, which is further enhanced on

stimulation (Groux et al. 1992; Meyaard et al. 1992), whereas spontaneous T-cell apoptosis is reduced in cells from LTNPs (Liegler et al. 1998). In vivo, apoptosis of infected, and to a greater extent of uninfected, bystander CD4 T cells has been noted (Finkel et al. 1995) and attributed to direct, e.g. virus-induced apoptosis of infected cells, and indirect, e.g. macrophage-mediated, apoptosis of uninfected CD4 T cells (Herbein et al. 1998).

Fas (CD95) expression on T cells from HIV-1-infected individuals is increased and its ligation induces apoptosis (Kobayashi et al. 1990; Katsikis et al. 1995). After the interaction of Nef with the T-cell receptor ζ chain, HIV also induces Fas ligand expression on T cells (Xu et al. 1999), whereas Fas ligand expression is increased on macrophages in the lymphoid tissue from HIV patients (Dockrell et al. 1998). Apoptosis of uninfected T cells can occur on interaction with Fas and secretion of tumor necrosis factor (TNF) α (Badley et al. 1997).

Moreover, cross-linking of CD4 with gp120 efficiently primes CD4 T cells for Fas-mediated apoptosis (Banda et al. 1992). Monocytes can bind immune-complexed gp120 via CD16, and thereby interact with CD4 on T cells and induce Fas-dependent apoptosis (Orlikowsky et al. 1997; Oyaizu et al. 1997). Importantly, various HIV proteins, e.g. Nef and Vpu, can downregulate CD4, thus avoiding death of infected $CD4^+$ T cells through this mechanism (Willey et al. 1992; Salghetti et al. 1995). Fas-independent mechanisms might contribute to accelerated T-cell apoptosis (Badley et al. 2000; Gougeon 2003). Thus, increased apoptosis of uninfected (and infected) T cells may critically add to the HIV-induced immunopathogenesis. Regulation of apoptosis in HIV-1 infection seems, however, to be complex, because various HIV gene products have been attributed to pro- as well as antiapoptotic functions (Badley et al. 2000; Gougeon 2003).

Activation-induced cell death

There is increasing evidence for a critical role of activation of the immune system and the induction of T-cell proliferation and, as its physiological consequence, AICD of uninfected cells in the immunopathogenesis of HIV infection. A prerequisite for AICD is the interaction of Fas and its ligand, and the expression of both molecules is significantly increased in HIV-1 infection, as discussed above.

Studies in HIV-1 patients before and after antiretroviral therapy suggested that T-cell proliferation is mainly driven by immune activation, suggesting AICD as an additional mechanism of CD4 cell depletion besides virus-mediated killing (Hazenberg et al. 2000). This immune activation is primarily the result of antigenic stimulation by HIV-1 itself, as well as opportunistic infections (Orendi et al. 1998; Cohen Stuart et al. 2000), correlating both with apoptosis and better with disease progression than plasma viral burden (Gougeon et al. 1996; Giorgi et al. 1999). Consistent with these findings are data obtained from HIV-2 infected patients. Here, lower levels of T-cell activation and apoptosis correlate with a better clinical prognosis, whereas HIV-2 patients with a similar level of immune activation as seen in HIV-1 infection also suffer from CD4 T-cell depletion despite significantly lower viral loads (Michel et al. 2000; Sousa et al. 2002). Similarly, both rhesus macaques and sooty mangabeys develop high viremia after SIV infection, but, although the macaques ultimately succumb to simian AIDS, mangabeys do not develop immunodeficiency correlating with differences in cellular and humoral immune responses (Kaur et al. 1998). It is interesting that the numbers of $CD25^+CD4^+$ T lymphocytes (regulatory T cells?) increase in infected mangabeys, whereas this cell population declines in macaques. Finally, although chimpanzees can be infected with HIV-1 but rarely develop immunodeficiency, increased levels of apoptosis and immune hyperactivation were seen in two animals who did develop a progressive loss of $CD4^+$ T cells after HIV-1 infection (Davis et al. 1998). The critical impact of immune activation on T-cell homeostasis was recently demonstrated in a murine study using CD70 transgenic mice where severe T-cell depletion, induced by chronic activation of CD27, led to lethal *Pneumocystis carinii* infections (Tesselaar et al. 2003).

Reciprocally, in chronic HIV-1 infection, the activation of latently infected cells favors the local transmission of virus in the lymphoid tissue, thereby supporting the viral life cycle (Grossman et al. 1998).

Altered T-cell migration patterns

Exposure of resting $CD4^+$ T lymphocytes to HIV-1 upregulated the homing receptor CD62L (L-selectin) on the cellular surface, thereby supporting the migration of these cells to the lymphoid tissue of SCID mice (Wang et al. 1997). Interestingly, signaling through these homing receptors (but not through other surface molecules) led to apoptotic cell death of immigrated CD4 T cells (Wang et al. 1999). Likewise, reinfused $CD4^+$ blood T lymphocytes of HIV-1 patients rapidly migrated and homed to lymph nodes and bone marrow at increased levels (Chen et al. 2002). Therefore, HIV-induced alterations of T-cell migration and homing may add to the decline of peripheral CD4 T cells in HIV-1 infection.

Impaired T-cell production

Regenerative dysfunction or failure of the bone marrow is commonly seen in late-stage HIV-1 patients, leading to suppressed hemopoiesis. Its origin, however, is often multifactorial, i.e. besides HIV-1 infection itself, opportunistic infections and the application of myelosuppressive drugs may considerably contribute to this development (Moses et al. 1998). As infection of $CD34^+$ hemopoietic progenitor cells is apparently rather low,

HIV-1-induced alterations of bone marrow functions are mostly the result of infected auxiliary cells and perturbations of cytokine secretion. In addition, dysfunction of the thymus caused by HIV-1 infection has been attributed to impaired T-cell production (McCune 2001).

In summary, HIV-1-induced immune activation and changes in T-cell homeostasis most probably lead to increased T-cell proliferation to maintain sufficient numbers of infectable CD4 T cells at the principal sites of viral replication, i.e. the lymphoid tissues, followed by cell death of infected and uninfected cells. Various mechanisms appear to contribute synergistically to the development of $CD4^+$ T-cell immunodeficiency that is paralleled by the decline of these cells in the periphery. The impact of these mechanisms on HIV-1 immunopathogenesis may vary in different populations of infected individuals, e.g. neonates and adults.

$CD8^+$ T LYMPHOCYTES

Specific $CD8^+$ CTLs combat HIV-1 infection by both lysis of target cells via the granule exocytosis pathway and the secretion of β-chemokines, i.e. RANTES (regulated on activation, normal T cell expressed and secreted, CCL5), MIP-1α (CCL3), and MIP-1β (CCL4), which block viral entry at the site of the co-receptor (Gandhi and Walker 2002). Other crucial soluble mediators secreted by CTLs and involved in inhibition of viral replication include the interleukin (IL)-16 (Baier et al. 1995) (see section on Cytokines) and α-defensins (Zhang et al. 2002).

An effective viral strategy to avoid lysis of infected cells is the emergence of escape mutants where changes in the epitopes interfere with peptide binding to the MHC molecule, leading to unrecognized target cells (Johnson and Desrosiers 2002). In addition, the phenotype and function of $CD8^+$ T cells can be altered and impaired at multiple levels. More sensitive in vitro assays have been developed for better detection of antigen-specific interferon (IFN)-γ-secreting cells in the blood or lymphoid tissues, because monitoring of tetramer-positive, HIV-specific cells does not necessarily provide information on the functional status of the cells. On application of these methods, significant numbers of HIV-specific CTLs unable to produce IFN-γ indicated impaired cellular functions (Goepfert et al. 2000; Shankar et al. 2000), whereas opposing results were found by others (Appay et al. 2000; Goulder et al. 2000). Recent data suggest a better correlation between tetramer staining and IFN-γ secretion early after infection, compared with later stages of the infection (Kostense et al. 2002). In addition, the impaired cytolytic capacity of $CD8^+$ T cells has been related to significantly lower levels of perforin in CTLs in the blood and lymphoid tissues from HIV-1 patients (Andersson et al. 1999; Appay et al. 2000).

Defects in $CD8^+$ T-cell-mediated immune responses in HIV-1 infection have also been detected at the level of antigen presentation. The viral protein Nef can downmodulate MHC I molecules on infected cells, resulting in reduced peptide presentation and thereby protection against killing by CTLs (Schwartz et al. 1996; Collins et al. 1998). In addition, downmodulation of the CD3 ζ chain expression and decreased expression of the protein tyrosine kinases and the signal-transducing molecules Lck, Fyn, and ZAP-70 in peripheral CD8 cells from HIV-infected individuals contributes to impaired T-cell receptor (TCR) signaling and is associated with disease progression (Stefanova et al. 1996; Trimble and Lieberman 1998). At the same time, the co-stimulatory molecule CD28 is downregulated on these cells (Vingerhoets et al. 1995; Trimble et al. 2000).

Other phenotypic distinctions of HIV-1-specific CD8 T cells are a persistent CD27 expression suggesting impaired maturation of the cells (Appay et al. 2000), and an enhanced expression of the activation markers HLA-DR and CD38 (Giorgi et al. 1994). The expression of CD38 correlates with rapid CD4 depletion whereas the presence of $HLA\text{-}DR^+CD38^-$ cells is associated with a better disease prognosis. Of additional importance may be the expression of HLA-class I-specific inhibitory receptors (iNKR) (De Maria and Moretta 2000). Similar to NK cells, $CD8^+$ T lymphocytes can express molecules from different families of receptors that can downmodulate T-cell functions, e.g. cytolytic activity, upon MHC I binding. In HIV-1-infection, increased expression of killer cell Ig-like receptors (KIR), as well as receptors from the lectin-type CD94/NKG2 family, has been shown for $CD8^+$ T cells. These $CD8^+iNKR^+$ T cells may further contribute to the HIV-1-induced impairment of cellular immune functions by enhanced secretion of IL-4 and IL-5 (De Maria et al. 2000). Notably, $CD8^+$ T cells from LTNPs express similar levels of iNKR as $CD8^+$ T cells from uninfected controls (Costa et al. 2003).

$CD8^+$ T cell homeostatic defects in HIV-1 infection comprise alterations in migration, proliferation, and cell death. Effector CTLs accumulate at considerably lower numbers in lymphoid tissues, the sites of the predominant viral replication (Pantaleo et al. 1997), and these migratory defects could be caused by a reduced expression of homing receptors to lymphoid tissue, e.g. CCR7 (Chen et al. 2001). A high turnover of CTLs has been observed in HIV-1-infected individuals, ultimately leading to the decline of HIV-1-specific and -unspecific CD8 cells (Sachsenberg et al. 1998; Kovacs et al. 2001). Death of CTLs has been attributed to lymphocyte-reactive autoantibodies or apoptosis induced by FasL-expressing HIV-infected cells (Wang et al. 1998; Mueller et al. 2001). Remarkably, HIV-1-specific $CD57^+CD8^+$ T lymphocytes were unable to proliferate on antigenic stimulation, but died of activation-induced apoptotic death (Brenchley et al. 2003).

The loss of CD4 help caused by the decline of CD4 T cells in the course of the disease might have a significant

impact on the failure of CD8-mediated HIV-1 control (Altfeld and Rosenberg 2000). HIV-1-specific proliferative responses correlate with levels of CTLs and inversely correlate with plasma viral load. In late stages of HIV-1 infection and in the absence of HIV-1-specific CD4 T cells, despite larger numbers of HIV-1-specific CTLs, the effector activity of these CTLs is markedly reduced (Spiegel et al. 2000). In vertically infected children, impaired CTL functions were seen in those with low CD4 counts but also in children younger than 3 years, indicating that the development of effective CD8 T-cell responses may take years (Sandberg et al. 2003). In summary, the data suggest considerably impaired (mainly HIV-1-specific) effector functions of $CD8^+$ T lymphocytes in HIV-1-infected individuals.

DENDRITIC CELLS

Dendritic cells (DC) can be subdivided into two phenotypically and functionally distinct populations, i.e. myeloid dendritic cells (mDC) and plasmacytoid dendritic cells (pDC). Myeloid DCs comprise most of the DC subsets characterized to date; potent antigen-presenting cells (APC) in the blood and peripheral tissues from where they migrate via the afferent lymphatics to the lymph nodes. In contrast, pDCs represent a unique cell population, able to secrete large amounts of type I interferons on stimulation and found only in the blood and lymphoid tissue, to which they migrate via the high endothelial venules. Both DC populations are of particular interest in the context of HIV-1 infection for their potent immunostimulatory capacities, although direct effects of HIV-1 on both subsets might significantly promote HIV-1-induced immunosuppression (Weissman and Fauci 1997; Siegal and Spear 2001; Frank and Pope 2002).

Myeloid DCs are probably the first cells that encounter HIV-1 during mucosal transmission of the virus (Steinman et al. 2003). Immature mDCs, such as Langerhans' cells (LC) in the epidermis, are located in the periphery directly under the epithelial layers and express the receptors required for viral entry, i.e. CD4 and chemokine receptors, at an immature state of differentiation, mainly CCR5 (Zaitseva et al. 1997). In addition, DC-SIGN (CD209), a recently identified C-type lectin receptor on the cell surface, can bind HIV-1 envelope glycoprotein gp120 and transfer the virus to T cells (Geijtenbeek et al. 2000). Its in vivo relevance remains controversial, however, because vaginal, but not rectal, epithelial mDCs are $CD209^-$ (Soilleux and Coleman 2001; Jameson et al. 2002), and, at least in the SIV macaque model, monocyte-derived DCs can transmit the virus independently of CD209 (Wu et al. 1999). Other lectins, such as langerin, might therefore primarily serve as HIV-1-binding sites on epithelial mDCs whereas emigrated DCs and pDCs may predominantly bind gp120 via CD4 (Turville et al. 2002). After binding and/or internalization of HIV-1, mDCs can hand over the virus to the $CD4^+$ T-lymphocyte compartment, thereby readily initiating viral replication in these cells either at the site of infection or in the draining lymph nodes. Viral replication in mDCs themselves is inhibited on maturation of the cells (Bakri et al. 2001). After the establishment of infection, only low numbers of infected mDCs, compared with $CD4^+$ T cells, can be found in the tissue and lymphoid organs (Steinman et al. 2003).

Although pDCs might significantly contribute to the early immune activation in HIV-1 infection, particularly through the secretion of IFN-α (Ferbas et al. 1994), they also co-express CD4 and various chemokine receptors (Penna et al. 2001), can be infected with HIV-1 in vitro (Patterson et al. 2001), and are therefore also possible targets of direct HIV-1 infection. Although the literature is controversial on this subject, both mDCs and pDCs may be impaired in numbers and/or functions in chronically HIV-1-infected individuals (Chehimi et al. 2002; Barron et al. 2003), and proviral DNA was recently detected in both mDC and pDC subsets in vivo (Donaghy et al. 2003). Thus, although both antigen-presenting mDCs and IFN-α-secreting pDCs are most probably involved in the innate and adaptive immune responses against HIV, dysfunctions of these cells may contribute to the immune suppression during HIV-1 infection, in particular in later stages of the disease.

MONOCYTES AND MACROPHAGES

Monocytes and macrophages express CD4 and, depending on their stage of differentiation, various chemokine receptors, and therefore serve as potential targets for HIV-1. Only low numbers (< 1 percent) of HIV-1-infected monocytes can be detected in the peripheral blood and bone marrow of HIV-1 patients (Kedzierska et al. 2003). Likewise, the in vitro infectibility of freshly isolated monocytes is limited and considerably less than in macrophages. In vitro culture and activation/differentiation of monocytes, however, allow a productive, yet noncytopathic, infection. There are conflicting data about whether macrophages contain increased amounts of HIV-1 as such compared with monocytes in HIV-1-infected patients. However, tissue macrophages can become a source of vigorous viral production in the context of opportunistic infections (Orenstein et al. 1997). Moreover, monocytes from HIV-1-infected patients produce high amounts of various proinflammatory cytokines, such as IL-1, IL-6, and TNF-α, which have been shown to promote replication of HIV-1 in vitro (Poli et al. 1990a, b).

A decline in chemotaxis and the in vitro survival of monocytes isolated from the peripheral blood of HIV-1 patients has been noted early (Smith et al. 1984; Muller et al. 1990b). Similarly, a decreased oxidative burst activity of monocytes and monocyte-derived macrophages was found (Muller et al. 1990a, b; Spear et al. 1990). Monocytes from HIV-1 patients also express fewer

co-stimulatory molecules than cells from uninfected controls, coinciding with impaired T-cell-stimulatory capacity (Miedema et al. 1988; Dudhane et al. 1996). Recent flow cytometry studies from whole blood obtained from HIV-1-infected patients indicated an activated phenotype of monocytes in vivo (increased CD11b and decreased CD62L, L-selectin, expression, as well as increased actin polymerization), enhanced H_2O_2 production, and decreased expression of the adhesion molecules sialyl-Lewis X and CD31 related to the disease stage of the patients (Elbim et al. 1999; Pillet et al. 1999).

Phagocytosis of *Staphylococcus aureus* by monocytes from AIDS patients was decreased (Pos et al. 1992), and ADCC and cytotoxic activity, via CD4 against gp120/41-expressing cells by HIV-1-infected macrophages, and monocytes from HIV-1-infected individuals, were reduced (Baldwin et al. 1990; Ahmad and Menezes 1996). How ever, normal or increased chemotaxis, phagocytosis, and superoxide anion release by monocytes from HIV-1 patients (Nielsen et al. 1986; Bandres et al. 1993), as well as normal or increased phagocytosis by alveolar macrophages, have also been reported (Musher et al. 1990; Gordon et al. 2001).

The macrophage mannose receptor (MMR), a pattern recognition molecule and C-type lectin, is involved in recognition and binding of *Pneumocystis carinii* (now known as *P. jiroveci*), an opportunistic pathogen frequently seen in AIDS patients. Consequently, the downregulation of the MMR in alveolar macrophages isolated from HIV-1-infected patients, which has been related to a Tat-mediated reduction of the receptor promoter activity, interferes with these functions (Wehle et al. 1993; Koziel et al. 1998; Caldwell et al. 2000). The additionally impaired oxidative burst response and an altered cytokine secretion by these cells in response to *P. carinii* may critically contribute to patients' increased susceptibility to *P. carinii* pneumonia (Kandil et al. 1994; Koziel et al. 2000). Further defects of macrophage antifungal activity may exist against *Histoplasma capsulatum*, *Aspergillus fumigatus*, and *Candida* spp. (Baldwin et al. 1990; Kedzierska et al. 2003).

Similarly, HIV-1-infected macrophages and monocyte(s)-derived macrophages isolated from AIDS patients displayed defects in phagocytosis and intracellular killing, together with reduced H_2O_2 production, of opsonized *Toxoplasma gondii*, another opportunistic infectious agent in HIV-1 patients (Delemarre et al. 1994; Biggs et al. 1995). Phagocytosis of opsonized *T. gondii* has been shown to be Fc receptor (FcR) dependent, and FcRs as well as complement receptors are actually decreased on macrophages on in vitro infection with HIV-1 and on monocytes from HIV-1-infected individuals, possibly related to changes in intracellular tyrosine phosphorylation (Kedzierska et al. 2003).

In summary, various HIV-1-related alterations of monocyte/macrophage phenotype and functions have been reported. Methodological problems may arise, however, from the evaluation of functions of primary tissue cells, such as macrophages, after in vitro generation, differentiation, and infection. These problems, as well as different experimental approaches and additional effects on monocyte/macrophage functions, e.g. by drug treatment, may account for some conflicting results.

B LYMPHOCYTES

HIV-1 infection exerts profound effects on the B-lymphocyte compartment, i.e. polyclonal B-cell activation with spontaneous secretion of HIV-1-specific as well as HIV-1-nonspecific antibodies, leading to hypergammaglobulinemia, accompanied by decreased B-cell responses to mitogens in vitro (Lane et al. 1983; Shirai et al. 1992). These in vivo and in vitro effects have been attributed to a newly appearing B-cell subpopulation expressing reduced levels of CD21 (Moir et al. 2001).

Viral gp120 has been shown to bind to B cells expressing immunoglobulin VH3 gene products and activate these as a superantigen (Berberian et al. 1993). This is followed by a decrease of this cell subset with changes being more prominent in activated 'memory' rather than resting B cells. It may contribute to impaired responses to bacterial infections and partly explain the frequency of pneumococcal infections in which B cells expressing VH3 genes are important for the antibody repertoire against polysaccharides (Janoff et al. 1992; Scamurra et al. 2000). In addition to viral components, membrane-bound TNF-α on HIV-1-infected $CD4^+$ T lymphocytes may critically be involved in these B-cell perturbations (Macchia et al. 1993).

Immaturity and activation of peripheral B cells in HIV-1 infection coincide with a loss of $CD27^+$ memory B cells (Martinez-Maza et al. 1987; De Milito et al. 2001) and elevated serum levels of soluble CD27 (Widney et al. 1999). This could be the result of an enhanced expression of the CD27 ligand CD70 by activated T lymphocytes, thereby stimulating memory B cells and driving their differentiation to Ig-secreting plasma cells resulting in hypergammaglobulinemia (Nagase et al. 2001). Virions bound to follicular DCs in lymph nodes might significantly contribute to the observed B-cell activation (Zamarchi et al. 2002), whereas activated B cells themselves can promote viral expression in T cells by TNF-α and IL-6 secretion (Rieckmann et al. 1991). Further, alterations in the B-cell compartment of HIV-1-infected individuals comprise significantly less IgA secretion at mucosal sites (Kotler et al. 1987), elevated IgE levels (Wright et al. 1990), and reduced HLA-DR expression by B cells (Ginaldi et al. 1998).

The chronic B-cell activation and concomitant loss of T-cell function promote the genesis of B-cell lymphoma in AIDS patients, and cytokine homologues encoded by additional viral pathogens, such as vIL-10 by Epstein–Barr virus and vIL-6 by the human herpesvirus 8 might significantly contribute to this development

(Martinez-Maza and Breen 2002). Thus, in HIV-1-infected patients several functional abnormalities of B lymphocytes and Ig production are seen that often precede the characteristic decline of peripheral $CD4^+$ T cells.

NEUTROPHIL GRANULOCYTES

Several studies have demonstrated altered neutrophil functions in HIV-1 patients. Increased oxidative burst activity was detected in neutrophils from HIV-1 patients (Murphy et al. 1988; Bandres et al. 1993), whereas others reported on unchanged or even decreased production of reactive oxygen intermediates, possibly resulting from previous activation in vivo (Nielsen et al. 1986; Roilides et al. 1990; Chen et al. 1993; Pitrak et al. 1993; Flo et al. 1994; Wenisch et al. 1996). Similarly, increased phagocytosis of *Staphylococcus aureus*, *Escherichia coli*, and *Candida* spp. (Bandres et al. 1993; Wenisch et al. 1996), but also a reduction in phagocytosis of bacterial and fungal pathogens, were reported (Pos et al. 1992; Gabrilovich et al. 1994). Several studies suggested considerably decreased intracellular killing of bacteria or fungi by neutrophils from HIV-1-infected individuals (Ellis et al. 1988; Murphy et al. 1988; Roilides et al. 1993; Wenisch et al. 1996), whereas two groups reported on unaltered killing of *S. aureus* and *Candida* spp. (Pos et al. 1992; Cassone et al. 1997). Further defects in neutrophils from HIV-1-infected individuals include reduced chemotaxis (Valone et al. 1984), accelerated neutrophil apoptosis (Pitrak et al. 1996), and a reduced 5-lipoxygenase metabolism, leading to lower leukotriene production (Coffey et al. 1998). Remarkably, a soluble factor in the serum of HIV-1 patients reduced the ability of neutrophils to opsonize bacterial pathogens (Ellis et al. 1988). Beside some neutrophil dysfunctions, HIV-1-patients may have neutropenia which occurs either induced by infection or, more often, as a result from myelosuppressive therapies.

In conclusion, the literature on potential dysfunctions of neutrophil granulocytes in HIV-1 patients is inconclusive, most probably the result of methodological differences. In addition, the patients included in these studies may not have been comparable over the stages of disease and pharmacological treatments with possible side effects on neutrophil functions. Nevertheless, non-neutropenic HIV-1-infected individuals apparently do not have invasive mycoses, such as aspergillosis or candidemia, to the same extent as patients who are neutropenic as a result of chemotherapy.

INNATE CYTOTOXIC CELLS (NK CELLS AND γδ T CELLS)

Natural killer cells are critically important in the early combat of viral infections. In HIV-1 infection NK cell-mediated direct lysis of infected target cells, ADCC, and cytokine secretion (especially of IFN-γ and TNF-α) represent important mechanisms that interfere with viral replication. Similar to NK cells, T lymphocytes bearing the γδ TCR are cytotoxic and can release proinflammatory cytokines. These cells constitute a small proportion (up to 10 percent) of peripheral $CD3^+$ T cells, and, in contrast to other immune cells, they recognize phosphorylated nonpeptidic microbial metabolites and alkylamines. Both ID="12332"NK and γδ T cells can additionally interfere with HIV-1 replication by the secretion of chemokines; in the case of NK cells an inverse relationship between this function and the level of viremia has been described (Malkovsky et al. 2000; Levy 2001; Kottilil et al. 2003).

There are various studies demonstrating increasingly impaired NK cell functions in HIV-1-infected individuals correlating with disease progression. Qualitative defects in cytotoxicity of NK and lymphokine-activated killer (LAK) cells in HIV-1-infected patients appear early during HIV-1 infection and are accompanied by a low NK cell responsiveness to IFN-α (Brenner et al. 1993; Ullum et al. 1995, 1999). A deficiency of tubulin rearrangement may significantly contribute to the reduced potency of the cells to kill target cells (Sirianni et al. 1988).

Binding of Ig to the FcγRIII (CD16) on NK cells initiates ADCC. A loss of cytolytic $CD16^+$ NK cells in the peripheral blood was described early, however (Brenner et al. 1989), and explains the profound defects of ADCC found in HIV-1-infected individuals (Brenner et al. 1991; Ahmad et al. 1994). Essential signaling molecules involved in the CD16-dependent cytolysis, i.e. ζ molecules, were found to be decreased in NK cells from HIV-1 patients (Geertsma et al. 1999). Moreover, a selective depletion of primarily cytotoxic, mature, $CD56^{dim}$ NK cells without major changes in the cytokine-secreting $CD56^{bright}$ population correlates with reduced NK cell activity (Hu et al. 1995; Tarazona et al. 2002). Simultaneously increased numbers of a more immature $CD16^+CD56^-$ NK cell subset may indicate a defective differentiation of NK cells in HIV-1 infection.

An important strategy of HIV-1 to escape NK cell-mediated lysis is the selective downregulation of HLA-A and -B, leaving HLA-C and -E on the cellular surface, thereby avoiding NK cell cytotoxicity (Cohen et al. 1999). Further phenotypic changes involve the expression of inhibitory cellular receptors on NK cells which can dampen their function on binding to MHC I molecules. C-type lectin receptors of the CD94/NKG2 family are upregulated on NK cells in HIV-1 infection whereas the results regarding KIR expression are controversial (Andre et al. 1999; Galiani et al. 1999).

Alterations also occur on the level of γδ T cells in HIV-1 infection. The majority (60–95 percent) of peripheral γδ T cells in healthy individuals express the Vγ9 and Vδ2 TCR chains and inhibitory NK cell receptors, mostly of the CD94/NKG2 complex, but lack both CD4 and CD8 molecules. In HIV-1 infection, this subset is considerably diminished and displays serious functional defects, including reduced secretion of IFN-γ

and TNF-α, which may contribute to the increased susceptibility of HIV-1 patients to opportunistic infections (Poccia et al. 1996; Wallace et al. 1997). At the same time, $V\delta1^+$ cells are significantly expanded in both bone marrow and peripheral blood of HIV-1-infected individuals (De Paoli et al. 1991; De Maria et al. 1992; Rossol et al. 1998). These cells represent an activated, potentially cytotoxic population, fully capable of proinflammatory cytokine secretion (Boullier et al. 1997), and a recent study suggests that these cells may contribute to HIV-1-associated immunopathogenesis through depletion of uninfected $CD4^+$ T lymphocytes (Sindhu et al. 2003). An inverse correlation of cytotoxicity with CD4 counts has also been reported for NK cells (Ahmad et al. 2001). Thus, alterations of subpopulations and/or functions of NK and γδ T cells may contribute to the overall immunosuppression observed in HIV-1 patients.

CYTOKINES

The secretion of IL-2, IL-12, and IFN-γ has been associated with protective immune responses to HIV-1; however, secretion of IL-2 is significantly reduced in HIV-1 patients, possibly as a result of the increased susceptibility of IL-2-producing Th1 cells to apoptosis (Clerici and Shearer 1994; Ledru et al. 1998). Similarly, IL-12 is produced in PBMCs significantly less from HIV-1 patients (Chehimi et al. 1994). The percentages and absolute numbers of Gag-specific $IFN\text{-}\gamma^+IL\text{-}2^+CD4^+$ T lymphocytes in the blood correlate inversely with viral loads in LTNPs (Boaz et al. 2002), and low IFN-γ secretion (by $CD8^+$ T cells and others) was related to disease progression (Ullum et al. 1997). Restoration of immune functions under antiretroviral therapy of HIV-1-infected infants is associated with increased IFN-γ and IL-2 secretion (Reuben et al. 2002).

The loss of the previously discussed cytokines and/or increased levels of IL-4 and/or IL-10 may favor disease progression in both HIV-1-infected infants and adults. In particular, IL-10 secretion has been attributed to T-cell dysfunction, disease progression, and poor prognosis in HIV-1 infection (Clerici and Shearer 1994). Notably, whole blood cultures recently revealed a reduced secretion of IL-10 as well as of TNF-α, IFN-γ, IL-1, IL-12, and IL-2 on stimulation with lipopolysaccharide (LPS) and phytohaemagglutinin (PHA), correlating with progression of HIV-1 (Ostrowski et al. 2003).

In HIV-1 infection altered secretion is also seen for other cytokines. Levels of IL-7 are increased, most probably as part of a homeostatic mechanism in response to T-cell depletion, and a reduced expression of its receptor (CD127) was found on $CD8^+$ T lymphocytes from HIV-1-infected individuals (Fry et al. 2001; MacPherson et al. 2001; Napolitano et al. 2001). Although IL-15 could potentially exert some beneficial effects on functions of various immune cells in HIV-1 infection (Waldmann and Tagaya 1999), it also stimulated the expression of inhibitory NK cell receptors on $CD8^+$ T and NK cells (Mingari et al. 1997, 1998). In addition, high IL-15 serum levels in HIV patients, which correlate with the extent of hypergammaglobulinemia, point towards a role for IL-15 in the pathogenesis of HIV infection (Waldmann and Tagaya 1999).

Levels of IL-16 are increased during the asymptomatic phase of HIV-1 infection, followed by a significant decline of IL-16 serum concentrations in disease progression (Amiel et al. 1999). IL-16 is secreted by CD8 cells and capable of inhibiting HIV-1 infection in CD4 T cells by repressing the HIV-1 promoter activity (Baier et al. 1995; Maciaszek et al. 1997). The reduction of activation-induced cell death of lymphocytes by IL-16 may contribute to a suggested protective role in HIV infection (Idziorek et al. 1998). T-cell clones from LTNPs produce significantly larger amounts of IL-16 than cell clones from asymptomatic or AIDS patients (Scala et al. 1997).

Both IFN-α and IFN-β possess similar in vitro activity against HIV-1. Paradoxically, high levels of IFN-α and IFN-inducible protein 10 are detected in HIV patients, associated with advanced disease (Stylianou et al. 2000). In addition, an acid-labile form of IFN-α with reduced antiviral activity in vitro and associated with poor disease prognosis has been described (DeStefano et al. 1982; Gendelman et al. 1992). Therefore, these data indicate that the altered production of various cytokines may add to the observed defects in cellular immune responses in HIV-1 patients.

Particular immune dysfunctions in distinct immune compartments

LYMPH NODES

One of the characteristic clinical signs of HIV infection is the development of generalized lymphadenopathy. Studies on lymph node biopsies revealed at least three distinct histological patterns: follicular hyperplasia, follicular involution, and lymphocyte depletion (Tenner-Racz et al. 1985; Biberfeld et al. 1987; Racz et al. 1991). Similar changes were found in the spleen (Falk et al. 1988). It must be emphasized that the changes described in lymph nodes from HIV-infected patients are not specific because follicular hyperplasia and follicular involution, in particular, can also be found in other pathological conditions such as bacterial infections, and in rheumatoid arthritis (Ewing et al. 1985; Stanley and Frizzera 1986). Changes in lymph nodes, however, mirror the progression of the disease, with implications for the pathogenesis of AIDS (Pantaleo et al. 1993).

Immunpathogenesis

HIV reaches the lymph nodes during PHI. The virus is trapped by follicular DCs and replicates in $CD4^+$ T cells.

HIV particles can be demonstrated in the germinal centers of lymph nodes by electron microscopy and immunohistology (for a review, see Pantaleo et al. 1993). Adhesion of HIV virions to the follicular DC network in lymph nodes and germinal centers may contribute to the B-cell activation observed during HIV infection. It could be further demonstrated that lymph nodes are the major reservoir for HIV in the human body (for a review, see Pantaleo et al. 1993). Indeed, in the early stage of HIV infection, levels of viral burden and replication are far greater in lymph nodes compared with peripheral blood. During this time about 25 percent of $CD4^+$ T cells in germinal centers are infected with HIV (for a review, see Pantaleo et al. 1993). In the early and intermediate stages of the disease viral particles in lymph nodes are restricted to germinal centers with follicular DCs. HIV accumulates in germinal centers complexed with Ig and complement trapped by the follicular DCs, in agreement with their role in antigen clearance and presentation (for a review, see Pantaleo et al. 1993). Follicular DCs in germinal centers induce increased expression of the HIV-1 co-receptor CXCR4 on surrounding $CD4^+$ T cells, thereby facilitating infection of these cells by HIV. In contrast to their central role in induction of protective immune response in other infections, follicular DCs in HIV infection promote and enhance the spread and replication of HIV by presenting the replication-competent virus to susceptible cells such as $CD4^+$ T cells and macrophages (for a review, see Pantaleo et al. 1993).

As antigen-activated lymphocytes migrate into and through lymph nodes, they may come into contact with HIV immune complexes on the surface of follicular DCs and infect themselves. This may explain the slow but steady decrease of $CD4^+$ T cells in the peripheral blood (for a review, see Pantaleo et al. 1993). In late stages of the disease germinal centers involute and the network of follicular DCs is destroyed. Thus, the virus is no longer trapped in the lymph nodes and can quickly spread unchecked, resulting in viremia, characteristic of late-stage disease – AIDS. Furthermore, the absence of an intact network of follicular DCs in the germinal centers of lymph nodes results in an impaired immune response toward other infections by an inadequate antigen presentation necessary for the maintenance of T- and B-memory responses (for a review, see Pantaleo et al. 1993). Besides the direct reduction in the number of follicular DCs in the germinal centers of lymph nodes during infection with HIV/SIV, a reduced chemokine production and a reduced expression of markers that are involved in the trafficking of follicular DCs may further contribute to progressing systemic immunodeficiency in the course of HIV/SIV infection (Choi et al. 2003).

THYMUS

The thymus is not necessary for normal T-lymphocyte function in adults because a subset of mature post-thymic peripheral T lymphocytes is self-renewing (Stutman 1978). However, when the normal T-lymphocyte pool is destroyed by infection with HIV, the thymus may be necessary for complete regeneration of T lymphocytes. In late stages of HIV-1 infection, pronounced lymphocyte depletion and destruction of the thymus are observed (Schnittmann et al. 1990). Work on CD45 isoform expression by the T-cell subset has provided evidence for defective thymopoiesis in AIDS because peripheral $CD4^+$ T cells, which appear after HAART in AIDS patients, are derived from a regeneration of peripheral, post-thymic, $CD45RO^+$, memory T lymphocytes and not from $CD45RA^+$, naïve T cells produced in the thymus (Ho et al. 1995).

As in lymph nodes, three different histopathological patterns were determined.

Thymitis

HIV-induced thymitis is characterized by irregularly shaped follicles, $CD8^+$ T-cell infiltration of the follicles, and the start of follicular DC network fragmentation (Prevot et al. 1992). Thymic epithelial cells are injured early in infection as seen in HIV-infected humans (Seemayer et al. 1984). The degree of thymic hyperplasia in early HIV-1 infection may be variable, but can lead to an abnormally enlarged thymus (Prevot et al. 1992).

Precocious involution

As with lymph nodes, the thymus of patients in the intermediate and late stages of HIV infection shows a thymic involution (Seemayer et al. 1984). This stage of the disease may be accompanied by the infiltration of plasma cells (Seemayer et al. 1984) and macrophages (Papiernik et al. 1992) in the fat adjacent to the cord of the involved thymus.

Thymic dysplasia

This is the final stage of thymus changes during HIV infection, characterized by epithelial rosette formation (Seemayer et al. 1984) and calcification or loss of Hassall's bodies (Seemayer et al. 1984).

HIV target cells in the thymus

Not only $CD4^+$ thymocytes but also immature triple-negative thymocytes, which express CD4 but at very low levels, are susceptible to HIV-1 infection (Schnittmann et al. 1990). A further separation of these triple-negative cells revealed that only $CD1a^+$, but not $CD1a^-$, triple negative thymocytes (presumably the most immature subset) can be infected by HIV-1 (Valentin et al. 1994). Interestingly, protease inhibitor-resistant HIV-1 strains, which develop in some patients treated with protease inhibitors, are impaired in their capability to replicate in thymus tissue (Stoddart et al. 2001). This would explain why patients

with increasing viral load resulting from protease-resistance do not have a fall in their $CD4^+$ T-cell count.

Immune reconstitution of the thymus in HIV-infected patients

Neither thymic transplantation (Ciobanu et al. 1985; Dwyer et al. 1987) nor substitution of thymus-derived hormones (Hermans and Clumeck 1989) in HIV-infected patients leads to convincing evidence of immune reconstitution. The introduction of an effective antiretroviral therapy – HAART – clearly has a beneficial effect on the immune reconstitution of the thymus, however (Sempowski and Haynes 2002). The restoration of thymic function during HAART could be better monitored by the development and introduction of a new assay of thymus function in adults (the measurement of T-cell receptor excition circles (TREC)) (Ye et al. 2003). Measurement of TRECs revealed a loss of TREC levels within naïve $CD4^+$ T cells, indicating reduced thymic output during HIV infection (Douek et al. 2001). Poor $CD4^+$ T-cell increase in patients with good virological response to HAART seems to be caused by low thymic output (Teixeira et al. 2001). Fortunately, most HIV-1 infected patients, adults (Franco et al. 2002) and children (Correa and Munoz-Fernandez 2002), show an increased thymic output of $CD4^+$ T cells, which seems to correlate with an increase in thymic size in adults during the treatment with HAART (Franco et al. 2002).

HIV AND THE GASTROINTESTINAL MUCOSA

The gastrointestinal tract is not only a potential portal for HIV entry, but also an organ that plays a central role in pathogenesis and secondary opportunistic infections (for review see Schneider et al. 1997a). During the course of HIV infection, most of the patients develop gastrointestinal symptoms. The intestinal immune system, represented by specialized local immune system termed gut-associated lymphoid tissue (GALT), has special features which seem to be involved during HIV/SIV infection (for a review, see Schneider et al. 1997a).

HIV infection of the gastrointestinal tract

As lamina propria lymphocytes (LPL) belong to the effector compartment, most of them are already activated and represent a memory phenotype which makes these cells susceptible to HIV infection without prior stimulation (Lapenta et al. 1999). The increased state of activation seems to be the major factor in increased HIV-1 replication in lamina propria $CD4^+$ T lymphocytes (Sheriff et al. 2004). The increased susceptibility to HIV infection of intestinal $CD4^+$ T cells may also result from the expression of a higher amount of the chemokine receptors CCR5 and CXCR4 (Anton et al. 2000). Indeed, independent of the route of infection, HIV/SIV can even be found early after infection in the lamina propria of the intestinal tract (Veazey et al. 1998; Kewenig et al. 1999). The virus content seems to be higher in the intestinal mucosa compared with the peripheral blood (Kotler et al. 1991; Fackler et al. 1998; Veazey et al. 1998; Kewenig et al. 1999), and this higher mucosal virus load seems to result from an increased replication or translation (Fackler et al. 1998). The major target cells in the lamina propria of the intestine are $CD4^+$ T cells and not macrophages (Meng et al. 2000). Experimental infection of rhesus macaques by atraumatic application of pathogenic SIV to the tonsils, a mucosa-associated lymphoid organ, leads to primary infection of $CD4^+$ T lymphocytes and not to infection of the DC-rich squamous epithelium (Stahl-Hennig et al. 1999). The epithelial cells of the intestinal mucosa are not productively infected but serve as virus transmitters (Bomsel 1997). The transepithelial transport of HIV-1 by epithelial and M cells is mediated by the same receptors: the galactosyl cerebroside molecule and the chemokine receptors CCR5 and CXCR4 (Yahi et al. 1992; Fotopoulos et al. 2002). There is in vitro evidence that HIV can be transported via M cells (Amerongen et al. 1991). It is interesting that primary intestinal epithelial cells selectively transfer R5 HIV-1 to $CCR5^+$ $CD4^+$ T cells of the lamina propria (Meng et al. 2002).

HIV-induced immune activation and the consequences for the gastrointestinal mucosa

The mucosal infection with HIV-1 induces a primary T-cell activation which may lead to ulcers – the so-called 'giant ulcer' – in some patients (R. Ignatius and T. Schneider unpublished data). An initial mucosal immune activation with high production of cytokines (R. Ignatius and T. Schneider unpublished data) may induce a hyperproliferative villus atrophy in the small intestine, as seen in HIV-infected patients and even in very early stages of SIV infection (Kotler et al. 1984; Kewenig et al. 1999). The massive immune activation with secretion of proinflammatory cytokines such as TNF-α will affect the barrier function, inducing a leak flux that may further contribute to diarrhea without the presence of secondary opportunistic enteric pathogens (Schafer et al. 2002; Schmitz et al. 2002). Mucosal inflammation in HIV-infected patients may reach levels comparable to those of patients with inflammatory bowel disease (Olsson et al. 2000).

Mucosal immunodeficiency

- $CD4^+$ T cells: the course of mucosal HIV/SIV infection is further characterized by a rapid and nearly complete loss of $CD4^+$ T LPLs (Lim et al. 1993a; Schneider et al. 1995), which occurs in the SIV model within 2 weeks after infection (Veazey et al. 1998; Kewenig et al. 1999). The decline of $CD4^+$ T cells in the intestinal mucosa is more pronounced, especially

in the early stages of the disease than in the peripheral blood (Figure 2) (Schneider et al. 1995). As measurements of $CD4^+$ T LPLs in this compartment are thus far based on percentages, it is not yet completely clear whether this reflects a real loss of $CD4^+$ T LPLs or is the result of a massive increase of $CD8^+$ T LPLs with a relative decrease of $CD4^+$ T lymphocytes, as is the case for other body compartments (Sopper et al. 2003). There is a preferential decrease of $CCR5^+CD4^+$ T cells, which express the mucosa-homing receptor α4β7 (CD103) in the peripheral blood of HIV-infected patients (Krzysiek et al. 2001). However, a selective reduction of $CD103^+CD4^+$ LPLs could not be found in late stages of the disease (Schneider et al. 1994).

- $CD8^+$ T cells: in the lamina propria, the percentage of $CD8^+$ LPLs is increased, which seems to be caused by an increase of activated $HLADR^+CD8^+$ LPLs and cytotoxic $CD11a^+CD8^+$ LPLs (Schneider et al. 1994). These activated cytotoxic $CD8^+$ LPLs may recognize HIV antigens and play a role in the control of HIV infection (Couedel-Courteille et al. 1997), but they could also be harmful by damaging the intestinal epithelium as in HIV-associated alveolitis (Autran et al. 1988).
- Natural killer cells: NK cells that can eliminate virus-infected and tumor cells were found to be reduced in the intestinal mucosa of AIDS patients, which may further facilitate infections and malignancies in the intestine (Schneider et al. 1994).
- Intraepithelial lymphocytes: the percentage of γδ receptor-positive intraepithelial lymphocytes (IEL) in the intestine of AIDS patients seems to be altered. Interestingly, reduced numbers of γδ IELs in the duodenum in late stages of the disease were associated with short survival expectancy (Nilssen et al. 1996).
- Macrophages: macrophages of the intestinal mucosa in HIV-infected patients are also impaired because the antigen-presenting subset is reduced (Lim et al. 1993b).
- B cells and mucosal humoral immunity: insufficient helper function of $CD4^+$ T LPLs is also indicated by the reduced proportion of IgA plasma cells in the large intestine of AIDS patients because terminal IgA B-cell differentiation is $CD4^+$ T-cell dependent (for a review, see Schneider et al. 1997b). Most investigators found a reduced IgA production in the intestine of HIV-infected patients and SIV-infected macaques (Kotler et al. 1987; Schafer et al. 2002). More impressive, however, is an increase in the production of the normally not predominant intestinal IgG (Janoff et al. 1994; Schneider et al. 1998; Schafer et al. 2002). As only secretory IgA exhibits the full protective immune function at mucosal surfaces (for a review, see Brandtzaeg et al. 1985; Mazanec et al. 1993) by immunoexclusion (Stokes et al. 1975), and even intracellular neutralization of viruses within epithelial cells (Bomsel et al. 1998), a predominance of IgG and a lack or decrease of IgA may reflect a breakdown of the mucosal immune effector arm. Indeed, a lack of or restricted secretory HIV/SIV-specific IgA production is found in HIV-infected humans and SIV-infected macaques (Janoff et al. 1994; Schneider et al. 1997a; Schafer et al. 2002). This local immune deficiency may further contribute to a rapid and massive spread of HIV/SIV in the intestinal mucosa (Kotler et al. 1991; Fackler et al. 1998; Veazey et al. 1998; Kewenig et al. 1999).

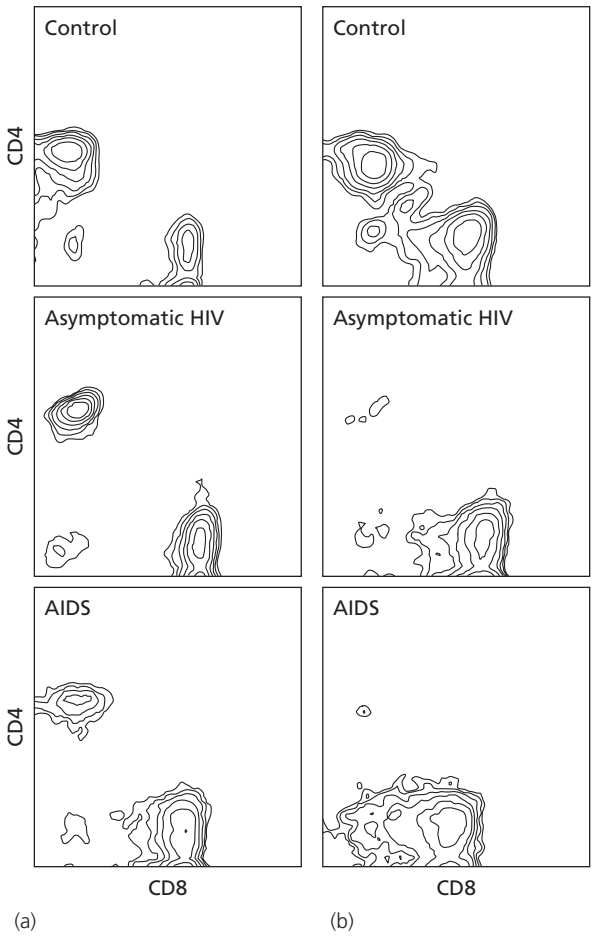

Figure 2 *Pronounced loss of CD4 $^+$ T cells in duodenal mucosa compared with the peripheral blood. Contour blots of two-color immunofluorescence profile of gated $CD3^+$ T cells isolated from* **(a)** *the peripheral blood and* **(b)** *the duodenum of a control patient, of an asymptomatic HIV-1-infected patient, and an AIDS patient. Logarithmic intensities for red fluorescence (CD4) and green fluorescence (CD8) are shown on the* y *axis and* x *axis, respectively (Schneider et al. 1995).*

Immune reconstitution under HAART

The immune reconstitution currently measured by the increase of $CD4^+$ T cells in the peripheral blood after installation of HAART is, beside the HIV RNA levels,

the central parameter in determining the success or failure of treatment (O'Brien et al. 1997). It still remains unclear, however, if all functions and the entire repertoire of $CD4^+$ T cells can be restored after prolonged infection with HIV (Connors et al. 1997). A three-phase T-cell reconstitution is generally seen after initiating HAART: (1) an early rise of memory $CD4^+$ cells, (2) a reduction in T-cell activation correlated to the decreasing retroviral activity, together with an improved $CD4^+$ T-cell reactivity to recall antigens, and (3) a late rise of naïve $CD4^+$ lymphocytes while $CD8^+$ T cells decline (Autran et al. 1997). In one study 20 patients treated with HAART were followed up for 12 months, and CD4 cell proliferative responses to cytomegalovirus and tuberculin antigens were monitored. The investigators were able to demonstrate that HAART can induce sustained recovery of CD4 T-cell reactivity against opportunistic pathogens in severely immunosuppressed patients (Li et al. 1998). The restoration of cytomegalovirus-specific $CD4^+$ T-cell response in HIV-infected patients treated with HAART could be further confirmed by more specific techniques (Komanduri et al. 1998). Immune recovery under HAART could also be observed for other opportunistic pathogens such as *Toxoplasma gondii* (Fournier et al. 2001). Nevertheless, there is lack of functional reconstitution of HIV-specific, CD4-mediated immune response after HAART. Only in some patients can an increase in HIV-specific neutralizing antibodies be detected (Kim et al. 2001). A stringent consequence of the immune recovery of HIV-infected patients under HAART is the impressive decrease in the incidence of opportunistic infections and Kaposi's sarcoma in HIV-infected patients since the introduction of HAART (Palella et al. 1998). Fortunately, immune reconstitution can also be achieved in HIV-infected children, even in those with late stage disease, with HAART (Ometto et al. 2002). One problem of the immune reconstitution under HAART is, in rare cases, the immune reconstitution inflammatory syndrome, which is characterized by an exuberant inflammatory response towards previously present opportunistic pathogens (Shelburne and Hamill 2003).

HTLV-1 INFECTION

HTLV-1 and disease

Human T-cell lymphotropic virus type 1 was the first recognized human retrovirus (Poiesz et al. 1980). The best-known disease linked to HTLV-1 infection is the adult T-cell leukemia/lymphoma (ATL) (Uchiyama et al. 1977). In 1985 a group of patients with a neurological disease known as tropical spastic paraparesis (TSP) was found to be seropositive for HTLV-1 (Gessain et al. 1985). Subsequently, a report from Japan described a neurological disorder as HTLV-1-associated myelopathy, now considered to be identical to TSP (Osame et al. 1986).

Chronic inflammatory arthropathy and uveitis seems to be a rare complication in HTLV-1-infected individuals (Sato et al. 1991; Mochizuki et al. 1996). Beside these diseases patients with ATL or carriers of HTLV-1 show impairment of cellular immune responses (Cappell and Chow 1987).

Epidemiology

The three major reported routes of transmission are sexual intercourse, administration of blood products, and mother-to-child transfer. In endemic areas seropositive persons are clustered around the families, reflecting the predominance of mother-to-child transmission. It is estimated that approximately 10–20 million people are infected by HTLV-1 (Franchini 1995).

HTLV-1 infection is present in widely scattered populations in the world. The best-studied areas are the islands of southwestern Japan, where approximately 20 percent of the adults are seropositive (Hinuma et al. 1982), and the Caribbean basin, which includes the West Indies, northern South America, and the southeastern USA, where 2–5 percent of black adults are seropositive (Schupbach et al. 1983). Other hot spots of HTLV-1 infections have also been reported from west and central Africa, Melanesia, India, the Middle East, and parts of South America (Ifthikharuddin and Rosenblatt 2000).

The virus

HTLV-1 virions are spherical, 100 nm in diameter, and composed of an internal core of structural proteins (p15, p24, and p19) surrounding the viral RNA and polymerase, and an outer layer of viral envelope glycoproteins (gp46 and gp21) anchored in a lipid membrane (Wong-Staal and Gallo 1985). The proviral genome of HTLV-1 encodes *gag*, *pol*, and *env* genes characteristic of all known retroviruses. Both ends of the proviral genome are flanked by noncoding direct-repeat sequences called LTRs. LTRs mediate proviral integration and contain *cis*-acting regulatory elements important for viral transcription, viral mRNA processing, and reverse transcription. Beside the genes for the structural proteins, HTLV-1 has additional open reading frames, which encode for the important regulatory proteins such as Tax and Rex (Franchini 1995).

HTLV-1 Tax is a 40-kDa protein essential for the viral life cycle and transformation of human T lymphocytes (Slamon et al. 1984). It usually localizes in the nucleus of infected cells, here it is capable of activating several cellular transcription factors resulting in an enhanced trancription of cellular genes such as the interleukins IL-1, IL-2, IL-3, IL-6, granulocyte–macrophage colony-stimulating factor (GM-CSF), c-*fos*, c-*cis*, c-*myc*,

vimetin, parathyroid hormone-related protein (PTHrP), transforming growth factor β1 (TGF-β1), MHC I, NF-κB, nerve growth factor, and TNF-β (Franchini 1995). Tax is also capable of transactivating the adhesion molecule ICAM-1 (Tanaka et al. 1996). Such promiscuous transactivation of numerous genes by Tax is thought to play a crucial role in neoplastic transformation of T cells and may also be of central importance for the development of T-cell deficiency in HTLV-I infection.

The 27-kDa regulatory protein Rex plays an important role in regulating viral mRNA processing and is essential for export of full-length *gag*/*pol* and single-spliced *env* mRNA from nucleus to cytoplasm (Hanly et al. 1989). Furthermore, Rex enhances the expression of the IL-2Rα-chain (Kanamori et al. 1990), whereas p12, another regulatory protein of HTLV-1, seems to downregulate the β and γ_c chains of IL-2R (Mulloy et al. 1996). The modification of the IL-2 receptor of HTLV-1-infected T cells by regulatory proteins may influence T-cell function and T-cell transformation in HTLV-1 infection.

HTLV usually infects T cells. However, the cellular receptor for this virus is unknown so far. Experiments with the HTLV-1 surface glycoprotein revealed binding on T and B cells, NK cells, and macrophages (Nath et al. 2003). The putative HTLV-1 receptor seems to be upregulated by T-cell activation (Manel et al. 2003; Nath et al. 2003), especially during early activation (Manel et al. 2003). Moreover, the amount of HTLV-1-infected cells in HTLV-1 carriers seems to be increased during inflammation of infectious diseases (Nishimura et al. 2003). For the spread of HTLV-1 between cells and between individuals, cell contact is required because naturally infected lymphocytes produce virtually no cell-free infectious HTLV-1 particles. After contact between an infected and uninfected T cell, a polarization of the cytoskeleton of the infected cell to the cell–cell junction is induced (Igakura et al. 2003). HTLV-1 core complexes and the HTLV-1 genome accumulate at the cell–cell junction and are then transferred to the uninfected cell (Igakura et al. 2003).

Natural course of HTLV-1 infection

ADULT T-CELL LEUKEMIA/LYMPHOMA

Adult T-cell leukemia/lymphoma is a proliferative disorder of T cells characterized by lymphadenopathy, hypercalcemia, lytic bone lesions, skin involvement, and hepatosplenomegaly (Takatsuki et al. 1985). The skin lesions of HTLV-1 infection are manifold, including diffuse papules, nodules, plaques, erythematous patches, and diffuse erythroderma. In the blood abnormal lymphocytes with convoluted nuclei – so-called flower cells – are found. The malignant T cells in ATL are mature $CD4^+/CD8^-$ and have increased IL-2R α chain (CD25) expression (Hattori et al. 1981). The lifetime risk of developing ATL in HTLV-1 patients is estimated at 1–4 percent (Tajima and Kuroishi 1985). The latent phase from infection to actual development of disease is estimated to be 30–50 years (Tajima and Kuroishi 1985; Murphy et al. 1989). This long incubation period implies that most adult persons developing ATL were infected during early childhood. The most frequent mode of HTLV-1 transmission during this time is breast-feeding by HTLV-1-positive mothers. After manifestation of ATL the prognosis is poor and depends on the disease subtype, which can be distinguished based on clinical criteria (Shimoyama 1991). One of the major reasons for death in ATL patients is the development of opportunistic infections because of the acquired immunodeficiency.

TROPICAL SPASTIC PARAPARESIS

Tropical spastic paraparesis is also is a chronic progressive demyelinating disease affecting the spinal cord and the white matter of the central nervous system (CNS) (Bhigjee et al. 1991). The lifetime incidence of TSP in HTLV-1-infected patients is less than 5 percent (Kaplan et al. 1990). The disease appears usually in the fourth decade of life and women are about twice as likely to be affected as men (Vernant et al. 1987). TSP and ATL rarely occur in the same patient (Kawai et al. 1989). Similar to acute disseminated encephalomyelitis in measles, an autoimmune process is thought to play a key role in the pathogenesis of TSP. Myelin and axon destruction is accompanied by infiltrating $CD8^+$ T cells (Bhigjee et al. 1991), and a high frequency of cytolytic T cells with specificity against the HTLV-1 regulatory protein Tax was found in TSP patients (Koenig et al. 1993). Recently, a cross-reactive epitope between Tax and human neurons was described (Levin et al. 2002). The progression from asymptomatic to symptomatic HTLV-1 infection seems to be triggered by the increasing production of proinflammatory cytokines such as IFN-γ and TNF-α by Tax-expressing cells (Furukawa et al. 2003). For both diseases, ATL and TSP, until now no effective treatment exists.

Immunosuppression

Patients with ATL are immunocompromised and at increased risk of dying as a result of opportunistic infections. The median survival time of patients with acute ATL is only 10 months (Shimoyama et al. 1991). Most deaths in patients with symptomatic HTLV-1 disease are caused by opportunistic infections (White et al. 1995). As in HIV-infected patients, in HTLV-1-infected ATL patients *P. carinii* pneumonia, cryptococcal meningitis, and other disseminated fungal infections are seen (Bunn et al. 1983), which indicate an impaired Th-cell function. In addition, herpesvirus co-infection such as cytomegalovirus, herpes zoster,

and generalized herpes simplex virus infection is frequent in ATL patients (Bunn et al. 1983).

In particular, hyperinfection with *Strongyloides stercoralis* is a common problem in ATL patients (Nakada et al. 1987; Sato and Shiroma 1989; Newton et al. 1992; Plumelle et al. 1997). This phenomenon may indicate a selective immune defect (Newton et al. 1992). A Japanese study showed that 58 percent of the patients with *S. stercoralis* infection are HTLV-1 positive and, of these, 67 percent had a monoclonal integration of HTLV-1 proviral DNA in their blood lymphocytes (Nakada et al. 1987). This leads to speculation that strongyloides infection may be a co-factor for the development of ATL. Leukemic cells of ATL patients suppress B-cell immunoglobulin secretion by a complex mechanism involving induction of suppressor cells after activation of normal suppressor cell precursors (Waldmann et al. 1984).

Immunity in HTLV-1-infected patients seems to be impaired even before diseases like ATL or TSP become apparent. Fungal and bacterial skin infections occur frequently (Kawano et al. 1985; LaGrenade et al. 1990) and may be a marker for the HTLV-1 infection in endemic regions (LaGrenade et al. 1990). Delayed-type hypersensitivity is suppressed in HTLV-1 carriers (Murai et al. 1990).

Double infections with HIV-1 and HTLV-1 have been reported, but it is not clear so far if this accelerates progression to AIDS (Bartholomew et al. 1987; Cleghorn and Blattner 1992; Gotuzzo et al. 1992).

MEASLES

Measles is a highly contagious viral disease. After a prodromal stage with fever, coryza, cough, and conjunctivitis, a generalized maculopapular rash appears. Introduction of measles into virgin populations, as well as endemic transmission in populations lacking access to adequate medical care, is associated with high mortality (Griffin 2001; Duke and Mgone 2003). Despite the successful development of a live attenuated vaccine, measles remains a major cause of mortality in children of developing countries, accounting for 1 100 000 deaths annually (Murray and Lopez 1997; Duke and Mgone 2003).

The virus

Morbilliviruses are distinct from other paramyxoviruses in that they form intranuclear inclusion bodies. Virions are pleomorphic and range in size from 100 to 300 nm. The envelope carries two viral proteins: transmembrane hemagglutinin and fusion glycoproteins. The nucleocapsid is packed within the envelope in the form of an asymmetrical coil. Nonstructural proteins encoded by the measles virus include the C and the V proteins. Both are dispensable for viral replication in vitro, but may play a role in viral pathogenesis in vivo (for a review, see Griffin 2001).

RECEPTOR USAGE

CD46 (membrane co-factor protein (MCP)) is expressed on human nucleated cells and was the first cellular receptor identified for the measles virus. An extended binding site within CD46, spanning the two short conserved domains, SCR1 and SCR2, most distal to the membrane, interacts with the measles virus transmembrane hemagglutinin protein; the binding sites for the natural ligands, the C3b/C4b complement components, map in SCR3 and SCR4. However, more recent studies have questioned the role that CD46 plays for measles virus not passaged in vitro. These and all other measles virus strains tested so far use CD150 (signaling lymphocyte activation molecule (SLAM)) as an entry receptor. The expression of CD150 on activated T and B cells, memory cells, and immature thymocytes seems to be compatible with the well-recognized tropism of measles virus for the cells of the lymphoid compartment (for a review, see Schneider-Schaulies and Ter Meulen 2002).

NATURAL COURSE OF MEASLES INFECTION

Immunopathology

Measles is typically a childhood infection spread by the respiratory route. Virus replication takes place first in tracheal and bronchial epithelial cells (Sherman and Ruckle 1958). There is evidence that the virus is acquired from the basolateral side of epithelial cells by tissue-resident macrophages and DCs (Mrkic et al. 2000). The virus is probably transported by these cells to local lymph nodes, where the measles virus replicates and spreads by cell-associated viremia to a variety of organs (Ruckle and Rogers 1957; Forthal et al. 1992). The primary target cell in the blood is the monocyte (Esolen et al. 1993), and the viremia is accompanied by leukopenia (Sergiev et al. 1960). Lymphoid organs and tissues such as the thymus, spleen, lymph nodes, appendix, and tonsils are prominent sites of virus replication (Hall et al. 1971). Infection of thymocytes with the measles virus leads to apoptosis of these cells and a prolonged decrease in the size of the thymic cortex (White and Boyd 1973). Measles virus spreads to numerous other organs, including the skin, kidney, lung, gastrointestinal tract, genital mucosa, and liver. In these organs the virus replicates primarily in endothelial and epithelial cells. Endothelial cell infection is accompanied by vascular dilatation, increased vascular permeability, mononuclear cell infiltration, and infection of surrounding tissue (Denton 1925). Bright-red spots with a bluish center, the so-called Koplik's spots, appear on the oral mucosa 1–3 days before the skin rash, are pathologically similar to it, and involve the submucous glands (Denton 1925).

Clinical course

The clinical picture of measles develops after an incubation period of 10–14 days. The first prodromal symptoms are fever, malaise, cough, and coryza. This prodrome usually lasts 2–3 days during which the Koplik's spots appear on the oral mucosa. The typical maculopapular rash then appears, first on the face and behind the ears, from where it spreads centrifugally to the trunk and extremities. The rash fades 3–4 days from the start. During this time lymphadenopathy, mild splenomegaly, and appendicitis may be present. Clinical recovery begins soon after the appearance of the rash (Figure 3).

COMPLICATIONS

Predictors of poor outcome are severe lymphopenia (Coovadia et al. 1978) and poor antibody response (Wesley et al. 1982). Mortality in infection with measles is more frequent at the extremes of age. Most of the fatal outcomes observed in measles occur in children in developing countries. Malnutrition increases mortality caused by measles, and measles in turn worsens malnutrition (Dossetor et al. 1977). Death is most often the consequence of secondary infections or the reactivation of persistent infections such as tuberculosis (Duke and Mgone 2003). Most of the severe life-threatening pneumonia observed during measles is the result of secondary bacterial and viral infections (Beckford et al. 1985; Quiambao et al. 1998). The reactivation and exacerbation of tuberculosis were already mentioned in medical textbooks of the nineteenth century, and in 1908 von Pirquet reported the disappearance of delayed-type hypersensitivity skin responses to tuberculin during a measles outbreak. More recently, the reactivation and spread of herpesvirus infections, especially in the respiratory tract, has been reported (Orren et al. 1981; Suga et al. 1992). Importantly, young children in developing countries frequently develop diarrhea as a result of secondary bacterial and protozoal infections, worsening the precarious nutritional status of these children during infection with measles (Greenberg et al. 1991). Secondary and reactivated infections complicate the natural course of measles and are often the cause of fatal outcomes, underlining the importance of immune suppression during infection with the measles virus.

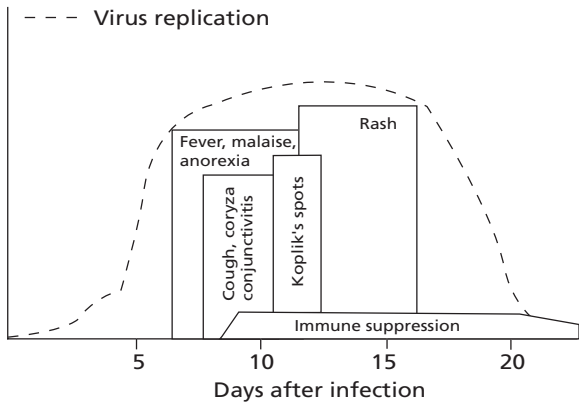

Figure 3 *Natural course of* measles virus *infection. Note that immune suppression begins usually 8–10 days after infection and before Koplik's spots and the skin rash appear. The duration of immune suppression exceeds that of clinical symptoms and may last up to 4 weeks after the rash has disappeared.*

Immunosuppression

Although the measles virus was the first pathogen recognized to cause immunosuppression, it was only recently that the underlying mechanisms were partially revealed. In vivo, delayed-type hypersensitivity skin test responses to recall antigens, such as tuberculin, are suppressed before the rash and for several weeks after apparent clinical recovery from measles infection (Figure 4) (Von Pirquet 1908; Tamashiro et al. 1987). Furthermore, cellular and humoral immune responses to new antigens during infection with measles are impaired (Coovadia et al. 1974). Isolated peripheral blood lymphocytes from patients with measles respond with reduced proliferation (Figure 5) and impaired cytokine production after stimulation with mitogens (Hirsch et al. 1984; Ward et al. 1991).

MONOCYTES AND DCS

Monocyte function is impaired by several mechanisms during measles. Both measles virus receptors, CD46 and CD150, are downregulated on the cell surface after contact with measles virus (for a review, see Schneider-Schaulies and ter Meulen 2002). The downregulation of CD46 may trigger lysis of uninfected lymphocytes by activating complement, as shown in vitro, and so may contribute to enhanced immune suppression. There is some evidence that CD46 can function, together with CD3, as a co-stimulatory molecule in the induction of T-cell proliferation and T-cell activation, which could as a consequence be blocked by measles-induced

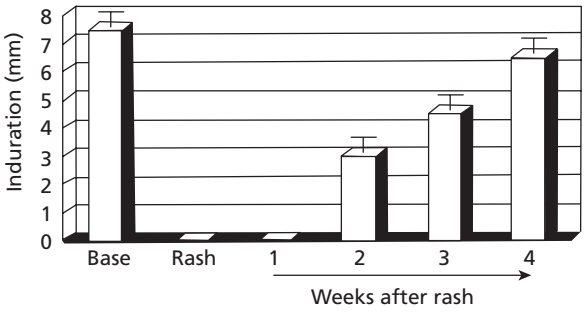

Figure 4 *Immune suppression during measles infection: changes in tuberculin-induced delayed-type hypersensitivity (DTH) skin test responses in children with measles who had previously been immunized against tuberculosis. (Modified after Tamashiro et al. 1987 and Griffin 2001, with permission.)*

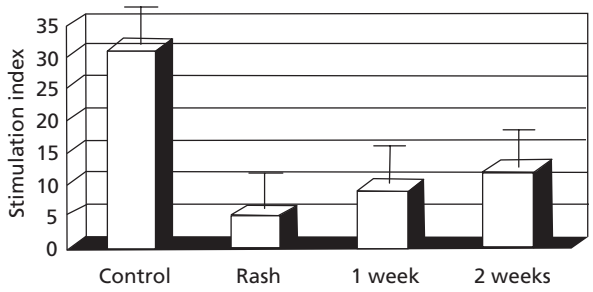

Figure 5 *Immune suppression during measles infection. Changes in proliferation of peripheral blood mononuclear cells to the mitogen phytohemagglutinin. (Modified after Hirsch et al. 1984, and Griffin 2001).*

downregulation. The downregulation of CD46 on monocytes infected with the measles virus results in a decreased IL-12 production (for a review, see Schneider-Schaulies and Ter Meulen 2002). The measles virus nucleocapsid protein inhibits IL-12 release from mouse monocytes. These observations are further supported by in vivo data showing a prolonged impairment of IL-12 production by monocytes from patients after natural measles infection. A decrease of IL-12 production by macrophages and monocytes may result in a decreased IFN-γ production by T cells. Furthermore, as stimulation of macrophages via CD46 seems to be involved in the response of macrophages to IFN-γ which stimulates the production of nitric oxide (NO) (for a review, see Schneider-Schaulies and Ter Meulen 2002). The downregulation of CD46 may result in a reduced production of NO and an altered immune response to intracellular pathogens such as mycobacteria.

The measles virus hemagglutinin seems to be responsible for CD150 downregulation (Tanaka et al. 2002). Recently, it could be demonstrated in an animal model that wild-type measles virus strains, which in contrast to vaccine virus induce strong immune suppression, exclusively used the CD150 and not the CD46 receptor (Pfeuffer et al. 2003). After infection and downregulation of CD105 on T cells, cell division and proliferation of these cells are inhibited (Hahm et al. 2003). Signaling events triggered after binding to this receptor are complex and can result not only in activation but also in cellular apoptosis (Sidorenko and Clark 1993). The IFN-γ production of $CD4^+$ T cells can be upregulated by ligation to the CD150 receptor (Aversa et al. 1997). Thus, downregulation of this molecule after infection with measles virus may impair Th1 responses toward intracellular pathogens, as seen in humans with measles (Griffin 1995). This hypothesis is further supported by recent experiments in transgenic mice expressing the measles virus receptor CD46. After infection with measles virus these animals were more susceptible to infection with *Listeria monocytogenes* as a result of the reduced number of macrophages and substantial defects in IFN-γ-producing $CD4^+$ T cells (Slifka et al. 2003). IFN-γ production is important for the defense of intracellular bacteria (Kaufmann 1992) and impairment in this pathway explains the observed increased bacterial infections during and after infection with measles. TNF-α production by monocytes is reduced during acute infection and recovery (Griffin et al. 1987). In vitro experiments with monocytic cell lines show a decrease in TNF-α production after infection with the measles virus (Leopardi et al. 1992).

The effect of the measles virus on DCs has not been clear until now. DCs isolated from peripheral blood showed normal release of IL-12 after stimulation with bacterial cell wall components; DCs generated in vitro, however, showed impaired production of IL-12 (for a review, see Schneider-Schaulies and Ter Meulen 2002). The reduced IL-12 production by DCs and monocytes may have consequences affecting the quality of T-cell responses and could explain an inadequate Th1 response during measles infection (Griffin et al. 1989; Ward and Griffin 1993). In fact measles virus-infected DCs are unable to stimulate allogenic T-cell proliferation, and even actively suppress in vitro-stimulation of T-cell proliferation (for a review, see Schneider-Schaulies and Ter Meulen 2002).

LYMPHOCYTES

A lymphopenia affecting both CD4 and CD8 cells is observed during infection with measles (Okada et al. 2000). Although the CD4:CD8 T-cell ratio normally remains unaltered (Arneborn and Biberfeld 1983), a greater decrease of $CD4^+$ T cells with decreased CD4:CD8 ratios has been found in children with malnutrition (Ryon et al. 2002). The mechanism responsible for the lymphopenia is thought to be measles-induced apoptosis of uninfected lymphocytes (Okada et al. 2000; Ryon et al. 2002). A selective loss of peripheral lymphocyte function-associated antigen ($LFA\text{-}1^{high}$)-expressing T cells was observed in the course of measles virus infection, and this could reflect aberrant lymphocyte trafficking by random homing to tissues (Nanan et al. 1999). This may also contribute to leukopenia. The role of leukopenia for measles virus-induced immunosuppression is unclear, because the duration of immune function impairment clearly exceeds the panlymphopenic phase of the disease (Okada et al. 2000).

One reason for the reduced T-cell proliferation in vitro to mitogens during measles infection and during the first weeks of convalescence is inadequate IL-2 production. Addition of recombinant IL-2 to lymphocyte cultures from patients with measles restores lymphocyte proliferation ability (Griffin et al. 1986; Ward and Griffin 1993). Investigation of other T-cell cytokines revealed low IFN-γ release and high IL-4 production compared with controls (Ward et al. 1991; Griffin and Ward 1993). In vitro neutralization of IL-4 with antibodies also improves lymphocyte proliferation (Griffin

and Ward 1993). This T-cell cytokine profile suggests a shift toward a Th2-type response and may explain the suppression of delayed-type hypersensitivity during and after the first weeks of infection.

In contrast to natural infection with measles virus, measles virus immunization does not result in a reduced IL-12 and IFN-γ production. Measles virus glycoprotein seems directly to block the proliferative response of lymphocytes to mitogens in vitro, whereas anti-measles virus antibodies and genetic exchange of measles glycoprotein abolish such inhibition of proliferation (for a review, see Schneider-Schaulies and Ter Meulen 2002). Direct in vitro infection of T cells results in a reduced proliferative response to mitogens and soluble antigens as well as in an impaired cytotoxic function (for a review, see Schneider-Schaulies and Ter Meulen 2002). IFN-α production is important to limit viral infections and infections with secondary viral infections, especially herpesvirus infections, which are frequently observed during and after measles virus infection (for a review, see Schneider-Schaulies and Ter Meulen 2002). In agreement with this clinical observation is the experimental finding that, after in vitro infection with measles virus, a suppression in the IFN-α-signaling pathway was documented (Yokota et al. 2003). Infection with the measles virus resulted in a suppression of Jak1 phosphorylation and association of the viral accessory proteins C and V with the IFN-α receptor complex (Yokota et al. 2003).

Infection of B cells in vitro with the measles virus reduces Ig production (Casali et al. 1984; Tishon et al. 1996). Measles virus nucleocapsid protein binds to activated B cells and reduces antibody production in vitro (Ravanel et al. 1997). However, in vivo experimental measles virus infection revealed an impaired T-cell function but no B-cell defect (Niewiesk et al. 2000).

Soluble factors such as cytokines and viral proteins account for the immunosuppression of infected and uninfected lymphocytes during and for several weeks after measles infection and seem to be more important than mechanisms directly induced by infection of T and B cells. However, the in vitro effects of infection of leukocytes, macrophages, and B and T cells by measles virus cannot be ruled out, and may also be relevant to the immune suppression observed during natural measles infection.

Impaired function of immunocompetent cells such as macrophages, DCs, and B and T cells can be found at different time points after measles virus infection. There seems to be a dichotomy between the immune response toward measles virus and other pathogens. This dichotomy may be resolved by investigations of a newly discovered regulatory $CD4^+CD25^+$ T-cell subpopulation. These cells are present after several infections in order to restrict and limit immune responses to certain pathogens, thus avoiding the induction of autoimmune diseases (Belkaid et al. 2002). The following scenario is therefore possible: after measles virus infection, a strong measles virus-specific T-cell and B-cell response is induced, which is capable of clearing the measles virus; after several days this immune response has to be restricted, and regulatory $CD4^+CD25^+$ T cells appear, which suppress and limit ongoing or newly induced immune responses; these cells may be active for several weeks, during which time the host is vulnerable to secondary infections.

New approaches to vaccine delivery

CHARALAMBOS D. PARTIDOS

The rationale for needle-free delivery of vaccines 1
Skin delivery of vaccines 2
Mucosal delivery of vaccines 9
Concluding remarks 14
References 14

THE RATIONALE FOR NEEDLE-FREE DELIVERY OF VACCINES

Vaccination has arguably had the greatest impact of any medical intervention on human health. Worldwide immunization/vaccination programs have been successful in significantly reducing the incidence of serious infectious diseases, such as poliomyelitis and measles, and eradicating smallpox. In many industrialized countries, effective immunization campaigns have resulted in a drop in incidence rates of the target diseases to such low levels that adverse reactions to vaccines rather than the diseases themselves have become a new area of awareness for the public (Andre 2001). To this end, public confidence and media coverage play a significant role in vaccine compliance. Participation rates in immunization programs drop rapidly after negative publicity about adverse effects of injecting vaccines (Miller and Pisani 1999). In addition, children normally associate the sight of a needle with pain which could result in a drop of the rate of compliance (Cohen et al. 2001). As an average, an infant receives 20–25 injections for immunization against different childhood infections by 18 months of age, there is considerable pressure to minimize vaccine-related visits by combining antigens and simplifying immunization procedures (Ward 2000; Jacobson et al. 2001). Needle-free immunization practices hold a great deal of promise in changing the public's attitude of 'being forced to get a shot' to seeking out vaccines.

Most vaccines are injectable preparations administered via parenteral routes. As a result, immunization requires needles and syringes and trained medical personnel, is expensive, normally does not induce mucosal immunity, and may lead to injection site reactions. In addition, in many instances, particularly in less developed countries, immunization may lead to infections by blood-borne pathogens as a result of the use of contaminated needles (Kane et al. 1999; Simonsen et al. 1999). Routine immunization programs account for about a billion injections per year (Kane et al. 1999) and such injections are believed to be safer than many nonimmunization injections (therapeutic injections) in most countries. However, the World Health Organization (WHO) has recently estimated that up to one-third of immunization injections are unsafe in four of six regions of the world (Miller and Pisani 1999). Several reports from countries in sub-Saharan Africa, Asia, and the Middle East have estimated that from 31 percent to more than 90 percent of childhood immunizations are unsafe (Simonsen et al. 1999). The main reasons for unsafe injections are: lack of sufficient quantities of syringes and needles, lack of operational sterilization equipment or fuel to operate such equipment, and patient demand for injections (Kane et al. 1999). Furthermore, there is a common misconception that it is safe to reuse syringes between patients if the needle is changed. In some countries, four of five disposable syringes, many of them supplied for immunization, are reused.

Population-based studies from China, India, and former Soviet states have shown unsafe injections to be a major source of hepatitis B virus (HBV) infection (Simonsen et al. 1999). In Egypt, nationwide injection campaigns against schistosomiasis between 1920 and 1980 played a major role in the extensive spread of hepatitis C virus (HCV) leading to the high current prevalence (18 percent) of the virus in the population

(Simonsen et al. 1999). It has been estimated that unsafe injections may cause 8–16 million HBV infections every year, 2.3–4.7 million HCV infections, and 80 000–160 000 HIV/AIDS infections (Kane et al. 1999). The transmission of hepatitis viruses and HIV are by no means the only risks involved with unsafe injections; many outbreaks involving other pathogens, such as Ebola and Lassa virus infections, and malaria have been reported (Simonsen et al. 1999).

With the availability of whole genome sequences, the potential number of candidate vaccine antigens has increased, and it is anticipated that the number of injections will increase further. Therefore, it is not surprising that the development of new approaches for their effective and safer delivery to the immune system ranks high in the WHO's priority list (Jodar et al. 2001). Safety is a major issue because vaccines are administered to prevent disease in healthy people (Clements et al. 1999). To increase compliance, as well as to make the vaccine more economical, vaccines should be effective after a single immunization using needle-free or noninvasive delivery systems.

Ideally, future vaccines should:

- be administered via noninvasive routes, such as the mucosae (436 m^2) and the skin (2 m^2) which cover a large surface area of the human body
- require only a single administration, or at the most two, to elicit protective immune responses
- be capable of immunizing at a very early age
- be available in formulations already combined with either multiple other vaccines or other vaccines at the moment of administration
- exhibit temperature stability to minimize the stringency of cold chain requirements.

New skin and mucosal vaccine delivery options (vaccine patches, nasal sprays, or edible vaccines) are promising to revolutionize the way that vaccines will be delivered in the future. Needle-free vaccine delivery systems will make immunization simpler, more economical, practical, and safer.

SKIN DELIVERY OF VACCINES

The skin barrier

The skin is the largest organ of the body (10 percent of body mass) and represents a readily accessible surface area for absorption (2 m^2 in adult humans). This offers a distinct advantage for exploiting the skin immune system for delivery of vaccines. The skin is made up of the epidermis and the dermis. The dermis (1–2 mm) contains fibroblasts, nerves, and blood vessels. The outermost layer of the epidermis, which constitutes an effective physical and chemical barrier, in the stratum corneum (10–20 μm thick in humans), is composed of keratinocytes anchored in a lipophilic matrix. Keratinocytes undergo terminal differentiation, a specialized form of programmed cell death. As a result, they lose their nuclei and crosslink, becoming resilient rigid corneocytes, and eventually they complex with lipids (Fuchs 1990). This is a well-regulated process required for the maintenance of the physiological thickness of the skin and the preservation of its barrier functions. Ceramides, cholesterol, and free fatty acids seem to play an important role in the corneocyte cohesion, contributing also to the permeability barrier of the skin (Morganti et al. 2001). Thus, the function of the skin is to preclude appreciable exchange of materials between the skin surface and the deep layers, and to protect against ultraviolet light.

Below the stratum corneum are layers of epidermis (50–100 μm) which are made up of keratinocytes at various stages of differentiation (Morganti et al. 2001). The stratum basale, just above the dermis, is the most metabolically active layer of the epidermis with large columnar cells. Interspersed among the basal keratinocytes are other cells, such as melanocytes, Langerhans' cells (LC), and sensory Merkel cells. Once keratinocytes leave the basal layer, they migrate upward via the stratum spinosum and stratum granulosum to the stratum corneum, acquiring the characteristics of fully differentiated corneocytes which are eventually sloughed at the skin surface. During this migration process, keratinocytes undergo morphological and biochemical changes necessary to discard their proliferative functions and adopt new protective roles.

The skin as a site of immune surveillance

As the skin is the principal interface with the external environment, it acts as an immune barrier protecting the host from invading pathogens. For this purpose, it is equipped with a unique set of immunocompetent cells, i.e. keratinocytes, and LCs, strategically located lymph nodes, and subsets of T lymphocytes that constitute the skin-associated lymphoid tissue (SALT) (Streilein 1983; Bos and Kapsenberg 1993). The intraepidermal lymphocytes constitute only about 2 percent of SALT and the majority are $CD8^+$ T cells (De Panfilis 1998; Debenedictis et al. 2001). The predominance of $CD8^+$ epidermal T cells is in contrast to the normal 2:1 ratio of $CD4^+$:$CD8^+$ T cells seen in peripheral blood; therefore, it is apparent that the population of T cells found in the epidermis is a special population of memory cells, which have selectively extravasated into the epidermis (Debenedictis et al. 2001). By contrast, the dermis contains both populations of $CD4^+$ and $CD8^+$ T cells in equivalent ratios (Debenedictis et al. 2001).

Keratinocytes, apart of being responsible for establishing the physical barrier of the skin (the viable

epidermis is composed of about 90–95 percent keratinocytes) and guaranteeing the structural integrity of the epidermis, produce a wide range of cytokines on activation by various stimuli. These include interleukins (IL), interferons (IFN), colony-stimulating factor (CSF), tumor necrosis factor (TNF), growth factors, and chemokines (Uchi et al. 2000). Resting keratinocytes synthesize and secrete low levels of cytokines. However, stimuli such as allergens, irritants, ultraviolet light, bacterial products, and physical trauma induce keratinocytes to produce significant amounts of cytokines (Uchi et al. 2000). These cytokines shape the local microenvironment of the skin to help maintain the appropriate balance of skin immune responses, and stimulate the maturation and migration of LCs. In particular, IL-1β and low levels of TNF-α are critically involved in the induction of LC migration from the skin (Wang et al. 1999). Keratinocytes do not just secrete cytokines; they also perform a scavenger function, eliminating foreign material from the intercellular spaces of the epidermis (Wolff and Honigsmann 1971) and responding to cytokines secreted by neighboring cells (Debenedictis et al. 2001). When they are exposed to IFN-γ produced by T cells, keratinocytes upregulate intercellular adhesion molecule 1 (ICAM-1) and class II major histocompatibility complex (MHC) antigens (keratinocytes do not constitutively express MHC class II molecules). This enables them to serve as accessory cells by providing co-stimulatory signals to support a T-cell-mediated response to bacterially derived superantigens, phytohemagglutinin, and anti-CD3 monoclonal antibody (Nickoloff et al. 1993).

LCs are powerful antigen-presenting cells (APC) (up to 1 000 cells/mm^2) that cover almost 20 percent of the surface area through their horizontal orientation and long protrusions (Debenedictis et al. 2001). They are of myeloid lineage, originally migrating to the skin during fetal development. LCs are defined by their dendritic morphology and the presence of a unique intracytoplasmic organelle, the Birbeck granule (Lappin et al. 1996). They are located at the basal layer of the epidermis as immature cells playing a sentinel role in the epidermis. LCs capture and process antigens and, during their migration via the efferent lymphatics to the paracortical T-cell areas of the draining lymph nodes, they mature and present antigenic peptides to naïve T cells. At this stage, they express co-stimulatory molecules of the B7 family, upregulate the surface expression of MHC class I and II molecules bound to peptides, and secrete high levels of proinflammatory cytokines, such as IL-12 and IL-1 (Lappin et al. 1996; Debenedictis et al. 2001).

Percutaneous absorption of antigens

Antigens applied on to bare skin penetrate across the continuous stratum corneum, mainly via the intracellular or intercellular routes (Barry 2001). However, appendages including hair follicles, or sebaceous or sweat glands can also serve as portals of antigen entry (Figure 1). The specific pathway that an antigen will follow depends on several parameters, such as its physicochemical characteristics and the method of antigen delivery. As the stratum corneum is lipophilic, antigens of a lipophilic nature would be better accepted (Naik et al. 2000; Barry 2001). Moreover, an antigen must be sufficiently 'mobile' to diffuse across the stratum corneum. Solute diffusivity has been shown to decrease exponentially as molecular volume (and hence molecular weight) increases, imposing a size restriction on favorable transport across the skin (Naik et al. 2000). After antigen diffusion through the stratum corneum, its re-partition into the more aqueous viable epidermis beneath would facilitate its move toward the basal layer, where LCs reside. Therefore, ideally, the antigen should possess both lipoidal and aqueous solubility for effective skin penetration (Naik et al. 2000; Barry 2001).

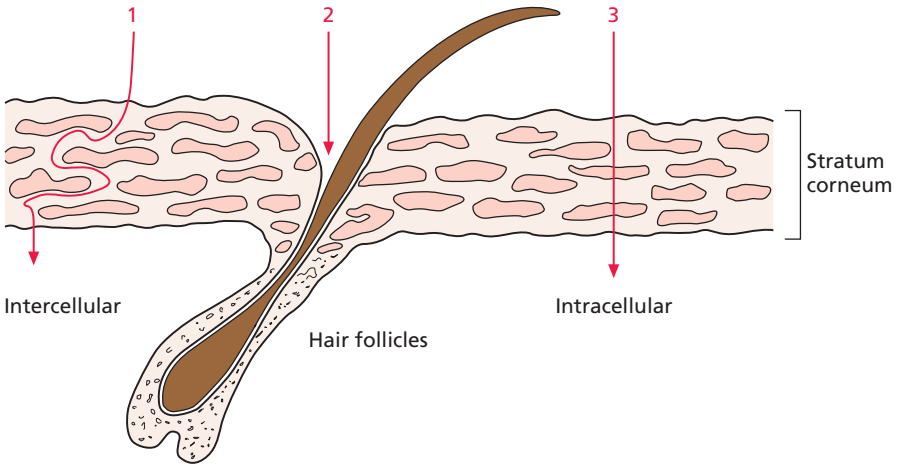

Figure 1 *Percutaneous absorption of antigens. Routes that an antigen can follow after application on to bare skin.*

However, when the skin is hydrated, its barrier functions are less pronounced and large molecules can pass through.

Studies on percutaneous absorption of various molecules have shown that the intercellular pathway is mainly favored by liposomes or low-molecular-mass uncharged molecules, whereas molecules delivered by electroporation or gene gun penetrate via the intracellular space (Morganti et al. 2001). Hair follicles could provide a shunt route through which large molecules, such as oligonucleotides, liposome-complexed DNA, or naked plasmid DNA (pDNA), can cross the stratum corneum (Prausnitz 1997; Fan et al. 1999; Morganti et al. 2001).

As stratum corneum lipids limit the transport of most compounds, efforts to increase percutaneous absorption have often focused on altering the lipid bilayer structure. This can be achieved by chemical or physical approaches. The most effective chemical enhancers act by disrupting or fluidizing lipid bilayer structures within the stratum corneum, thereby increasing the diffusion of molecules through the skin (Prausnitz 1997; Faldvari 2000; Barry 2001). Chemical enhancers such as dimethyl sulfoxide, unsaturated fatty acids, or surfactants have been shown to increase percutaneous absorption of small molecules (Prausnitz 1997). However, they frequently cause significant skin irritation and may affect the stability of co-administered molecules. For these reasons they have little practical impact beyond preclinical studies.

Liposomes have been shown to increase topical and transdermal delivery of various low-molecular-mass molecules. In particular, lipid-based biphasic delivery systems are capable of encapsulating compounds such as proteins and DNA and delivering them effectively through the skin, e.g. formulations with recombinant *Pasteurella haemolytica* leukotoxin and hen egg lysozyme can induce strongly polarized, T-helper 2 (Th2)-type, antigen-specific, immune responses after topical application (Baca-Estrada et al. 2000a). Transdermal delivery of lipid-based DNA vaccines can induce both antibody and cytokine responses in mice, although the responses are weak (Baca-Estrada et al. 2000b). When formulating vaccine antigens with liposomes, it is critical to determine the compatibility of the antigen with the liposome because different antigens can have different chemical properties that influence their formulation. Furthermore, the composition of the lipid-based delivery systems can influence their percutaneous absorption (Babiuk et al. 2000). To improve the absorption of topically applied liposomes, ultradeformable liposomes termed 'transferosomes' have been developed (Cevc et al. 1998). These carriers can cross the intact mammalian skin with an efficacy close to 100 percent, and ensure an efficiency of delivery greater than 50 percent. After topical application, they have been shown to increase the immunogenicity of incorporated Gap junctional proteins (Paul et al. 1998). Their mechanism of skin penetration appears to be related to their ability to squeeze through polar channels on hydration gradients (Cevc et al. 1998).

One of the physical enhancement technologies that has been tested for transdermal vaccine delivery is electroporation (Vanbever and Préat 1999). It uses high-voltage, short-duration pulses that induce: (1) a disorganization of the stratum corneum lipid bilayers; (2) an increase of skin hydration; and (3) a decrease of skin resistance. It permeabilizes keratinocytes without affecting skin viability in vivo (Dujardin et al. 2002). Skin electroporation was shown to increase immune responses to a myristilated peptide derived from hepatitis B surface antigen (HBsAg) when administered without adjuvant but not to a larger size antigen, such as diphtheria toxoid (DT) (Misra et al. 1999). This suggests that small antigens can be targeted in sufficient amounts to the LC-rich area of the epidermis, to mount a good immune response. However, there are still limited in vivo data concerning immunogenicity and skin toxicological studies for establishing the clinical value of this method.

A novel technology known as transdermal powder delivery (TPD) represents an alternate physical method for vaccine delivery. This method uses a supersonic flow of gas to accelerate vaccine-coated particles to a sufficiently high speed to enable them to penetrate the outer layers of the skin. The particles are sufficiently hard and robust not to deform significantly or shatter on impact, and penetrate the epidermis and dermis proportional to the product of their velocity, diameter, and density. A single administration of influenza vaccine using a helium-powered device elicited serum antivirus IgG antibody titers that were significantly higher than those induced by either intramuscular or subcutaneous injection. A booster administration resulted in a further increase of antibody titers and 100 percent protection against homologous virus challenge (Chen et al. 2000). Similarly, powderject delivery of DT was increased by 25- and 250-fold when 1 μg DT was co-administered with alum or a CpG motif, respectively. The induced antibodies neutralized the toxin and were long lasting, and their isotype was dependent on the adjuvant used (Chen et al. 2001a). Epidermal powderject immunization was also effective in eliciting mucosal immunity after administration of an inactivated influenza virus (Chen et al. 2001b), and cytotoxic T-cell responses after delivery of HBsAg or a synthetic peptide from influenza virus nucleoprotein (Chen et al. 2001c). The efficacy of this system can be attributed to the fact that it delivers vaccine antigens to LCs.

Another physical approach to vaccine delivery is the use of needle-free jet injectors (JI) that deliver the dose of vaccine at high velocity into dermal and subcutaneous layers with high-pressure fluid. Needle-free injectors have the potential to eliminate the risk of

accidental needlestick injuries after injections and during discard of waste. However, vaccine administration with JIs has been associated with higher levels of pain in female recipients, reported at the time of immunization, as well as with the occurrence of local injection site reactions in comparison to vaccine administration with needles and syringes (Jackson et al. 2001). When four types of injectors were tested for their safety, all were found to transmit significant (>10 pl) volumes of blood, although the volumes and frequency of contamination varied with the injector (Hoffman et al. 2001). This raises the risk of transmission of infectious diseases, such as HBV. Also a problem associated with the use of needle-free jet injection devices is that currently they cost several times what less developed countries now pay for conventional syringes and needles. In addition, a healthcare worker is required to administer the vaccine.

Immunization on to bare skin

For a long time it was thought that the skin barrier was impermeable to large molecules, but studies by Glenn et al. (1998a) have demonstrated that topical application of cholera toxin (CT) on to hydrated skin can induce strong systemic and mucosal immune responses and confer protection against lethal mucosal toxin challenge (Glenn et al. 1998b). CT is an exotoxin secreted by *Vibrio cholerae*. It is made up of five identical B subunits that bind with high affinity to G_{M1} gangliosides at cell surfaces and a single A subunit. The latter, after proteolytic cleavage, generates the enzymatically active A1 peptide, which activates adenylyl cyclase (Spangler 1992). A similar effect was demonstrated with another adenosine diphosphate (ADP)-ribosylating exotoxin, the heat-labile enterotoxin (LT) of *Escherichia coli* (Glenn et al. 1999; Beignon et al. 2001). Parallel to their immunogenic potential, these molecules act as adjuvants, potentiating immune responses to topically co-applied antigens, including toxoids (Scharton-Kersten et al. 1999; Hammond et al. 2000), proteins (Glenn et al. 1998a; Scharton-Kersten et al. 1999; Partidos et al. 2001), peptides (Beignon et al. 2001, 2002a), and viruses (El-Ghorr et al. 2000; Hammond et al. 2001a). It is the combination of their binding activity and built-in adjuvanticity that make these molecules powerful immunogens and adjuvants. When recombinant CTB, which is devoid of ADP-ribosylating activity, was used as an adjuvant with DT, anti-DT antibody responses were of a lower magnitude than those of the group in which CT was used. However, when a small amount of CT was added to the recombinant CTB, the adjuvant activity was restored to levels comparable to that of CT (Scharton-Kersten et al. 2000). In another study, preincubation of CT with G_{M1} gangliosides before topical application significantly reduced the serum and mucosal anti-CT antibody responses (Beignon et al. 2001).

Following these initial observations, the potential of skin as a noninvasive route for vaccine delivery has been demonstrated with several types of antigens:

- viruses: herpes simplex virus (HSV), adenovirus, inactivated rabies virus, recombinant mengo virus
- parasites: *Dirofilaria immitis*
- plasmid DNA: HBsAg, influenza antigens
- bacterial toxins (CT, LT), toxoids (tetanus toxoid (TT), DT)
- proteins: bovine serum albumin (BSA), β-galactosidase
- peptides: Th, B, cytoxic lymphocyte (CTL) epitopes.

Also, preliminary results from a phase 1 trial conducted in human volunteers (Glenn et al. 2000) have shown that topical application of LT with a patch: (1) does not induce local or systemic adverse reactions – only one volunteer developed a mild dermatitis at the adhesive site; (2) elicits anti-LT IgG responses that were boosted after the second and third topical application of LT; (3) induces long-lasting immunity and detectable anti-LT IgG or IgA antibodies in urine and stools; and (4) visualizes enlarged and rounded LCs using anti-CD1a staining at the site of immunization after 24 and 48 h.

Overall, these findings suggest that the skin barrier is not as highly resistant to permeation by antigenic molecules as previously thought, but rather has variable resistance. However, it should be noted that, in certain instances of skin disease, i.e. atopic dermatitis or psoriasis, as well as in skin wounds and burns, the permeability of the skin is increased as a result of alterations of its lipid content (Morganti et al. 2001).

CHARACTERISTICS AND REQUIREMENTS FOR APPLYING VACCINES ON TO BARE SKIN

Immunization on to bare skin is a needle-free and pain-free immunization procedure, which delivers antigens into the epidermis by simple topical application (Figure 2). With the experimental evidence that has been accumulated so far, some general rules can be drawn for vaccine application on to bare skin.

Skin hydration

Hydration of the skin before vaccine application appears to disrupt the barrier function of the stratum corneum to absorption. An increase in hydration of the skin is associated with a swelling of the stratum corneum and a softening of its texture (Barry 2001). Water is the most natural penetration enhancer that strongly binds to the keratin of corneocytes and increases the 'hydrophilic' character of the stratum corneum (Barry 2001). Glycerol has also been evaluated for its potentiating effects on the immune responses to CTB after topical application. Combination of hydration with glycerol enhanced the anti-CTB antibody responses approximately two- to

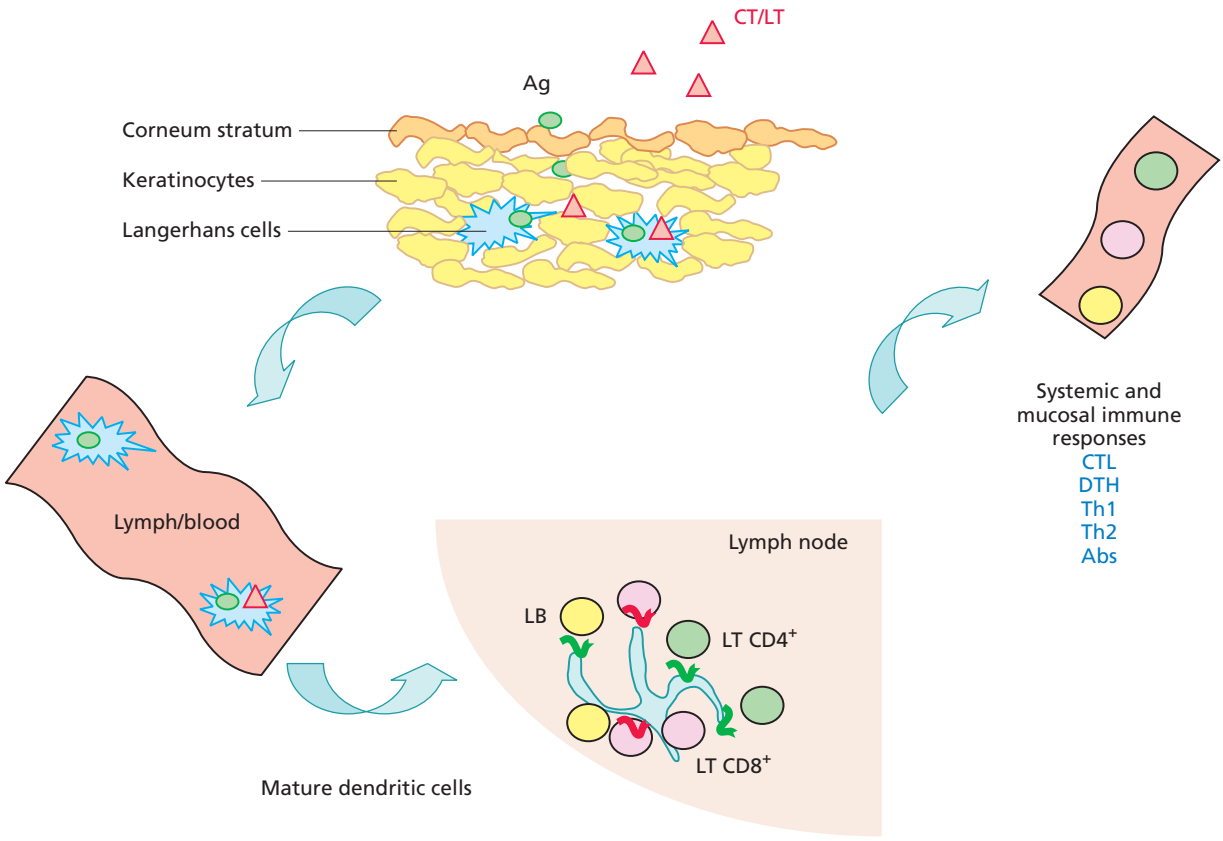

Figure 2 *Immunization on to bare skin. After penetration of vaccine formulation across the stratum corneum, the antigen is taken up by Langerhans' cells (LCs) and, in the presence of the co-administered adjuvant, they mature and migrate to the regional lymph nodes, where they present antigenic peptides to naïve T cells. This results in the induction of antigen-specific humoral and cellular responses.*

fourfold in comparison to the responses measured in mice with skin that was not hydrated (Hammond et al. 2001b).

The requirement of an adjuvant

Adjuvants are important to potentiate immune responses to antigens and ADP-ribosylating exotoxins, such as CT and LT, are suitable adjuvants for skin immunization. They enhance the antibody and T-cell responses to the co-administered antigen without signs of toxicity, normally associated with their mucosal delivery (when high doses are used). Furthermore, the anti-toxin antibody response does not interfere with the immune responses to co-administered antigen. Therefore, the same adjuvant can be used for multiple applications. The selection of adjuvant is also critical for the induction of long-lasting immunity and type of Th response. Several other adjuvants have been tested for skin immunization, such as synthetic oligodeoxynucleotides (ODN) containing CpG motifs, lipopolysaccharide (LPS), muramyl dipeptide (MDP), alum, IL-2, and IL-12 (Scharton-Kersten et al. 2000):

- ADP-ribosylating exotoxins (CT, pertussis toxin (PT), LT)
- mutants of ADP-ribosylating toxins (LTK63, LTR72, LTR192G)
- dangerous signals (LPS, CpG motifs, MDP)
- cytokines (IL-1b, IL-2, IL-12, TNF-α, GM-CSF).

Although they enhanced the antibody titers to co-applied antigen, the responses were short-lived and weaker than those induced in the presence of CT or LT.

Both CT and LT elicit predominantly Th2-type responses that might have a detrimental effect in individuals sensitive to allergic reactions. Normally, some adverse reactions to immunization are common and tolerated for the benefit of immunity. In several instances high levels of IgE responses have been noticed with DT vaccines (Mark et al. 1995). Although the exact role of IgE responses remains to be elucidated, there is always the possibility that the presence of high levels of IgE might be associated with high risk of anaphylaxis, particularly in individuals with atopic predisposition (Sakaguchi and Inouye 2000). On the other hand, antigen-specific IgE appears to correlate with protection in diseases such as schistosomiasis (Khalife et al. 2000). Therefore, successful immunization protocols will be needed to induce the appropriate types of immune responses in a selective and reliable way.

Beignon et al. (2002a) have demonstrated the possibility of modulating immune responses to topically applied antigens. Co-application of a promiscuous (non-MHC-restricted) Th epitope from influenza virus hemagglutinin (amino acids 307–319) with CT and an ODN containing a CpG motif on to hydrated bare skin of mice elicited peptide- and virus-specific $CD4^+$ T cells, increased the levels of IFN-γ and IL-6 secretion, and downregulated the total serum IgE antibody levels. CpG motifs have been shown to induce activation and maturation of LCs (Hartmann et al. 1999). Furthermore, their injection into the dermis enhances the expression of MHC and co-stimulatory molecules by LCs, and promotes their migration (Ban et al. 2000). Thus, it appears that CpG motifs can act synergistically with CT to promote a Th1-type of response. The exact series of events that lead to this synergistic effect is not yet clear. Similarly, mutants of LT with no or residual toxicity have been shown to enhance antigen-specific antibody and T-cell responses after topical immunization (Scharton-Kersten et al. 2000; Beignon et al. 2002b). Furthermore, the mutant LTR72, which retains some residual toxicity, was shown preferentially to stimulate the secretion of high levels of IFN-γ whereas the mutant LTK63, which is devoid of toxicity, did not (Beignon et al. 2002b).

Topical application of DNA vaccines

The success of topical application of DNA vaccines on to untreated skin depends on the ability to transfect effectively cells of the epidermis that will subsequently express the encoded antigen in sufficient quantities to elicit an immune response (Shi et al. 1999). It appears that the production of very small amounts of protein in the skin is sufficient to elicit an immune response. LCs and dermal dendritic cells (DC), which are specialized in initiating immune responses, can acquire antigen through direct transfection or through uptake and presentation of antigen synthesized by transfected keratinocytes or other skin cells (Pfutzner and Vogel 2000). The application of pDNA expressing the lacZ and HBsAg on to intact skin resulted in the induction of anti-HBsAg antibody and cellular responses (Fan et al. 1999). The predominant isotype of antibodies was IgG1, suggesting a Th2-type of response. For the HBsAg, the antibody and cellular responses were of the same order of magnitude of those induced after intramuscular injection with the commercially available recombinant HBsAg vaccine (Fan et al. 1999). Finally, in the same study it was demonstrated that efficient uptake of pDNA required the presence of intact hair follicles. Thus, the distal part of the human hair follicle immune system appears to represent a specialized compartment, where interacting intraepithelial T cells and LCs can generate effective immune responses (Christoph et al. 2000). The feasibility of topical genetic immunization has also been demonstrated with chitosan-based nanoparticles containing plasmid DNA (Cui and Mumper 2001). Two types of nanoparticles were investigated: (1) pDNA-condensed chitosan nanoparticles and (2) pDNA coated on preformed cationic chitosan/carboxymethylcellulose (CMC) nanoparticles. After their application on to bare skin, antigen expression was detectable at quantifiable levels in mouse skin after 24 h, and antigen-specific antibodies were measured in serum samples.

Induction of mucosal immunity

Immunization on to bare skin of mice with ADP-ribosylating exotoxins mixed with proteins elicits not only serum antibody responses but also significant levels of IgG and more modest levels of IgA antibodies in serum and multiple mucosal secretions (Glenn et al. 1999; Gockel et al. 2000; Beignon et al. 2001; Yu et al. 2002). Secretory IgA antibodies can decrease the colonization of mucosal surfaces by a number of microorganisms, and can effectively neutralize viruses and bacterial toxins generated within the lumen of the gut. In addition IgG antibodies present in mucosal fluids have recently been demonstrated to neutralize viruses (Baba et al. 2000). Thus, topical immunization provides an effective means to induce both systemic and mucosal immunity.

The exact mechanisms involved in the induction of mucosal immunity are still not clear. Studies by Enioutina et al. (2000) have provided evidence that 1,25-dihydroxy-vitamin D_3 [$1,25(OH)_2D_3$], which is derived from normal circulating 25-hydroxy-vitamin D_3 ($25(OH)D_3$) after its exposure to the enzymatic activity of 1α-hydroxylase, redirects the migration of dendritic cells from the skin into lymphoid organs committed to initiating mucosal immune responses. CT and LT, as a result of their ability to activate adenylyl cyclase, share the capacity to elevate intracellular levels of cAMP (Spangler 1992). Taking into account that the vitamin D_3–1α-hydroxylase gene, encoding the cellular enzyme that converts $25(OH)D_3$ to $1,25(OH)_2D_3$ is under cAMP control (Kong et al. 1999), it could be argued that ADP-ribosylating exotoxins stimulate the induction of mucosal immunity through the stimulation of $25(OH)D_3$–1α-hydroxylase expression (Enioutina et al. 2000).

Variability of immune responses and potential of peptides as immunogens

Data from immunogenicity studies using proteins, toxoids, and viruses suggest that large molecules can penetrate the skin barrier and with the help of an adjuvant elicit immune responses (Hammond et al. 2001b). However, antibody responses to co-applied antigens are normally variable, significantly lower, and with slower onset compared with those induced by co-application

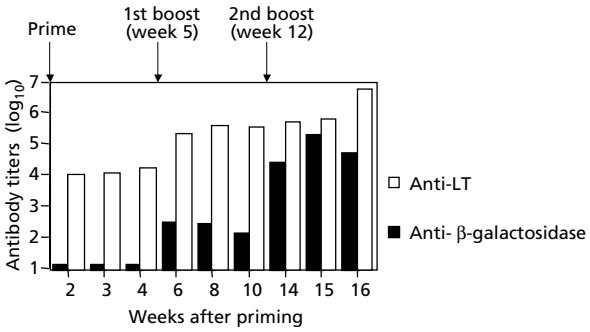

Figure 3 *Kinetics of serum anti-heat-labile enterotoxin (LT) and anti-β-galactosidase antibody responses after co-immunization on to bare skin of BALB/C mice (n = 6) with 100 μg LT and 100 μg β-galactosidase. Data represent mean of antibody titers.*

with CT or LT (Figure 3). Moreover, in a recent study where the safety and immunogenicity of a prototype enterotoxigenic *E. coli* vaccine was assessed in adult volunteers after topical application, only 68 and 53 percent were found to have serum anti-colonizing factor CS6 IgG and IgA antibodies, respectively (Guerena-Burgueno et al. 2002).

The use of synthetic peptides that normally have a small molecular size could potentially overcome this problem. This view is supported by the observation that most of the commonly used and effective drugs applied to bare skin have a molecular mass of <500 Da. In addition, chemicals that cause allergic contact dermatitis are <700 Da (Bos and Meinardi 2000). Peptide antigens have indeed been reported to induce protective anti-tumor CTL responses after application on to disrupted (by stripping) skin (Seo et al. 2000). This mechanical intervention removes the stratum corneum and activates LCs (through the stimulation of cytokine secretion by keratinocytes). Therefore, immune responses can be induced without the need of an adjuvant (Katoh et al. 1997); however, this procedure is painful and poorly reproducible. Recent studies have demonstrated that peptides are effective immunogens when co-applied with an ADP-ribosylating exotoxin or mutants of LT on to bare skin, eliciting peptide- and antigen-specific $CD4^+$ T cells (Beignon et al. 2001, 2002a, 2002b). This is particularly important in the context of vaccine design and delivery, because $CD4^+$ T cells produce cytokines that have a direct effect on viruses, help B cells to produce neutralizing and protective antivirus antibodies, and enhance the magnitude of cytotoxic cell responses to clear virus-infected cells.

FUTURE PROSPECTS AND CHALLENGES FOR DELIVERING VACCINES ON TO BARE SKIN

Over the last few years there has been remarkable progress in the field of immunodermatology. More recently, the realization that the skin has a number of characteristic features, such as easy accessibility, the presence of powerful APCs, and cells such as keratinocytes that secrete a wide range of cytokines, makes it an attractive route for vaccine delivery. However, for effective delivery, several variables related to the nature of the antigen and characteristics of the skin barrier must first be overcome, e.g. the diffusion of an antigen through the stratum corneum is dependent on its physicochemical properties and its molecular interactions with skin constituents (Morganti et al. 2001). These variables are:

- variability of percutaneous absorption as a result of the site, disease, age, species differences, and physicochemical characteristics of the vaccine formulation
- dermal metabolism of topically applied antigens
- incomplete understanding of the technologies that may be used to facilitate absorption and mechanisms of immune induction.

This could explain the differences in immunogenicity of several antigens after their application to bare skin. It is also important to stress the fact that the increased immunogenicity of ADP-ribosylating exotoxins depends mainly on their inherent adjuvanticity and ability to bind to cell surface receptors. Furthermore, the skin of humans and animals both pose unique barriers resulting from differences in anatomy and physiology between species, e.g. small laboratory animals always present a skin barrier that is more permeable than that of larger animals, including humans (Wester and Maibach 1987). The primary difference between rodent and human skin is the lipid composition and organization of the stratum corneum (Bond and Barry 1988). For these reasons, all these variables make the task of extrapolating the findings of studies performed in different animal species to the target species difficult. Percutaneous absorption through porcine and monkey skin (squirrel and rhesus) is more closely related to that through human skin (Wester and Maibach 1987). Porcine skin has been shown to be histologically and biochemically similar to human skin and, in addition, has permeability characteristics similar to that of human skin (Wester and Maibach 1987; Dick and Scott 1992); as such, it provides the most suitable experimental model for dermatological research on humans.

In situations of skin disease, eczematous reactions can develop after topical application of protein allergens on the nonlesional skin of atopic dermatitis patients, demonstrating that high-molecular-mass proteins could penetrate through this type of skin and induce an allergen-specific, delayed-type hypersensitivity response (Castelain 1995). This suggests that the skin can be a site of sensitization to environmental protein allergens. Therefore, topical application of vaccines might be an unsuitable option for immunization of individuals with skin disease. The main challenge ahead is the development of approaches to increase the permeability of the skin barrier to various vaccine antigen formulations, and

to optimize the induction of long-term mucosal and systemic immune responses.

MUCOSAL DELIVERY OF VACCINES

The mucosal routes offer an attractive alternative to currently used parenteral immunization. This is mainly because vaccines can be easily administered via the nose or orally, and mucosal immunization stimulates the induction of both systemic and local immunity. The latter is of paramount importance because most invading pathogens enter the body via mucosal surfaces. Over the last few years significant progress has been made in understanding the immunological mechanisms involved for maintaining the balance between immunity and tolerance. This has helped in the design and development of new immunization strategies and technologies, promising to deliver future vaccines via the mucosal routes using edible preparations or nasal sprays.

Antigen uptake by the mucosal surfaces

The mucosal surfaces constitute a vast surface area (about 300–400 m^2 in an adult), permanently challenged by numerous exogenous microorganisms associated with infectious diseases. As a consequence, the mucosal epithelium has evolved into a sophisticated physical and immunological barrier, protecting the host from environmental pathogens. Its cellular organization (stratified epithelium versus simple epithelium) and antigen-sampling mechanisms differ, depending on the mucosal site (Table 1).

The stratified epithelium is composed of multiple layers of cells that lack tight junctions. However, its barrier function is provided by a glycoprotein that they secrete, which seals the intercellular space and excludes the entry of most infectious agents and vaccines (Neutra et al. 1996). In stratified epithelia, DCs migrate to the outer limit of the epithelium, where they sample antigens for subsequent presentation in local or distant organized lymphoid tissues (McWilliam et al. 1994). Simple mucosal epithelia are made up of a layer of epithelial cells and their barrier function is provided by tight junctions that seal the intercellular space (Neutra et al. 1996). Antigens are sampled by microfold (M) cells that transport them from the lumen to the organized lymphoid tissue within the underlying mucosa. These are specialized epithelial cells located in the dome region of the epithelial layer, known as follicle-associated epithelium (Neutra 1999). Parallel to their sampling function, M cells can also serve as a portal of entry for several microorganisms, including bacteria, viruses, and protozoa (Siebers and Finlay 1996). Adherence to M cells has also been shown greatly to facilitate antigen transport and enhance immunogenicity (Frey and Neutra 1997; Wu et al. 2001).

Mucosa-associated lymphoid tissue and induction of immune responses

The mammalian mucosal immune system has evolved to fulfill several functions, including: (1) the production of secretory IgA (sIgA) antibody responses; (2) the distribution of effector B and T cells to local and distant mucosal sites; and (3) the induction of tolerance. The mucosa-associated lymphoid tissue (MALT) can be divided into two anatomically and functionally distinct compartments or sites: (1) the inductive sites, which are defined lymphoid microcompartments, and (2) the effector sites, which contain diffuse accumulations of large numbers of lymphoid cells that do not associate into apparently organized structures (McGhee et al. 1992). In the upper respiratory tract of rodents and humans, the major inductive sites are the nasal associated lymphoid tissue (NALT), which is organized lymphoid tissue at the base of the nasal cavity and the tonsils, respectively (Kuper et al. 1992). Mucosal inductive sites of the gastrointestinal tract include the Peyer's patches (PP), appendix, and solitary lymphoid nodules, which collectively comprise gut-associated lymphoid tissue (GALT).

The antigen is first encountered in the inductive sites, which contain B and T lymphocytes and APCs, and initial responses are elicited. After sensitization, antigen-specific B and T lymphocytes migrate from the inductive sites to regional lymph nodes and proceed via the lymph into the circulation, from where they 'home' to distant mucosal effector sites, such as the lamina propria of the respiratory, gastrointestinal, and reproductive tracts and

Table 1 *Types of mucosal epithelia and antigen-sampling mechanisms*

Type of epithelium	Mucosal site	Antigen-sampling
Stratified epithelia	Lower genital tract Upper digestive tract	APCs migrate to the outermost limit of the epithelium where they sample antigens
Simple epithelia	Lower digestive tract Airways	Migrating APCs can sample antigen
	Upper genital tract	Resident M cells transport antigens across the epithelial barrier

APCs, antigen-presenting cells; M, microfold.

the lacrimal, salivary, and mammary glands where immune responses are expressed. This cell distribution from the inductive sites to the effector sites has been termed the 'common mucosal immune system' (McDermott and Bienenstock 1979) and ensures that all mucosal surfaces are furnished with antigen-specific immunocompetent cells for protection.

Following mucosal immunization, humoral and cellular immune responses can be developed. After the antigen is sampled and passed through endocytic vesicles to the underlying lymphoid cells in the submucosa, antigen processing and presentation occur. This results in the activation of T cells which in turn provide help to B cells to develop into IgA plasma cells. Secretory IgA plays an important role in mucosal defense by providing protection against viruses or bacteria, and neutralizing microbial toxins (McGhee et al. 1992). These functions appear to be facilitated, at least in part, by the high-affinity binding of sIgA to mucus. Intranasal immunization induces sIgA responses to a wider range of mucosal tissues than does oral immunization. This is probably caused by the more promiscuous profile of homing receptors possessed by the circulating IgA-secreting cells that is induced after intranasal immunization (Quiding-Jarbrink et al. 1995).

For the induction of an effective mucosal immune response, the activation of T cells ($CD4^+$ and $CD8^+$) is of paramount importance because they provide help to B cells to become IgA-producing cells. These cells also release cytokines and chemokines that are involved in all aspects of mucosal immunity and, finally, they contribute to clearing viral infections. As $CD4^+$ T cells mature in response to foreign antigens, they take on unique characteristics normally manifested by production of a distinct set of cytokines. The Th1 cells, which result after infection with viruses or intracellular bacteria, produce IL-2, IFN-γ, and IL-12, and the Th2 cells, which are triggered by exogenous antigens, produce IL-4, IL-5, and IL-10 (Mosmann and Coffman 1989). Some of these cytokines regulate the expression of B-cell Ig isotypes and subclasses as well as influence the maturation of B-cell responses through induction of terminal differentiation into plasma cells.

Edible vaccines

The idea of using genetically modified plants to produce and deliver protective antigens via the oral route has several attractive features:

- Edible vaccines can be easily produced at low cost. The cultivation, harvesting, storage, and processing of transgenic crops could use the existing infrastructure and therefore would require relatively little capital investment. In this way, the purchase price of a dose of vaccine can be significantly reduced, increasing the chances of sustainable immunization strategies, particularly in less developed countries where vaccines are still expensive. It has been estimated that the cost of producing recombinant proteins in plants could be 10- to 50-fold lower than producing the same protein in *E. coli* (Kusnadi et al. 1997).
- There is a reduced health risk from pathogen contamination because plants do not harbor human infectious pathogens.
- Edible vaccines have the added advantage of providing natural bioencapsulation to the expressed antigens, protecting them from degradation in the harsh environment of the stomach.
- Edible vaccines induce mucosal immunity that can be advantageous for the control of pathogens entering via the mucosal surfaces and causing enteric, respiratory, and sexually transmitted infections.
- They can be administered easily and have the potential to deliver multiple immunogens, so increasing vaccine compliance.
- They can deliver multiple antigens.

EDIBLE VACCINES EXPRESSING VIRAL ANTIGENS

In 1992, Mason and co-workers successfully integrated the DNA-encoding HBsAg into tobacco plants. The expressed HBsAg retained its capacity for self-association and, more importantly, was structurally and antigenically similar to the HBsAg derived from human serum and recombinant yeast. Subsequent studies have demonstrated that oral immunization of mice with HBsAg expressed in potato tubers with CT as an adjuvant elicited strong serum antibody responses that reached a peak of 103 mIU/ml 4 weeks after the third dose and >10 mIU/ml (level of protective serum anti-HBsAg antibodies) at week 11 (Kong et al. 2001). Oral feeding of potato tubers expressing HBsAg has also resulted in strong memory responses, as assessed by the rise of antibody titers to 3 300 mIU/ml 3 weeks after parenteral immunization with a subimmunogenic dose of alum-absorbed recombinant HBsAg (Kong et al. 2001). Thus, the strategy of combining the oral and parenteral routes of immunization can be advantageous in less developed countries where the logistics of multiple delivery doses of parenteral vaccines have hampered global HBV immunization efforts. In the same study it was demonstrated that cooking the transgenic potatoes (boiling) before feeding mice significantly reduced the immunogenicity of the edible vaccine. An alternate approach to overcome this problem could be the use of transgenic bananas, which are grown extensively throughout the less developed world and, in contrast to potatoes, can be eaten raw.

As degradation of proteins in the stomach limits their bioavailability, much higher concentrations of antigens are normally required for effective oral immunization compared with parenteral immunization. Therefore,

increasing the levels of antigen expression in plant tissues would enhance the utility of transgenic plants as a source of recombinant antigen. A systematic study of factors influencing the accumulation of HBsAg in transgenic potatoes has demonstrated a striking improvement of antigen expression. This resulted from alternate polyadenylation signals and fusion protein-targeting signals designed to enhance integration or retention of HBsAg in the ER of plant cells (Richter et al. 2000). However, there is always the risk that a single high dose or repeated low doses of a protein antigen can induce oral tolerance. To overcome this potential problem, mucosal adjuvants that enhance antigen-specific mucosal and systemic immune responses have been used (Mason et al. 1996).

Another example of edible vaccine is the expression of Norwalk virus capsid protein (NVCP) in transgenic plants (Mason et al. 1996). The virus is responsible for an acute gastroenteritis in humans. The expression of recombinant NVCP in transgenic tobacco leaves resulted in self-assembled virus-like particles that were morphologically and physically similar to the recombinant protein produced in insect cells. When extracts of tobacco leaves expressing the NVCP were given orally (50 μg protein with or without 10 μg CT on days 1, 2, 11, and 28) by gavage to mice, both IgG and secretory IgA anti-NVCP antibodies were detected in serum and fecal samples. The presence of CT enhanced antibody levels during the early phases of immunization but, at the final time point (40 days after the first immunization), the titers in mice fed with transgenic tobacco with or without CT were very similar (Mason et al. 1996). In a human clinical trial, ingestion of raw transgenic potatoes constitutively expressing the NVCP induced immune responses in the absence of adjuvant (Tacket et al. 2000). The majority (95 percent) of volunteers had a significant increase in the number of antigen-specific IgA antibody-secreting cells, 20 percent developed antigen-specific serum IgG antibodies, whereas, in 30 percent of the volunteers, antigen-specific IgA antibodies were detected in their stools. In terms of safety, there were few symptoms other than nausea and cramps. More importantly, none of the volunteers had a change in serum anti-potatin (the major protein contained in potatoes) IgG antibodies after ingesting the transgenic potato vaccine (Tacket et al. 2000).

EDIBLE VACCINES EXPRESSING BACTERIAL ANTIGENS

The feasibility of using transgenic plant expression systems for vaccine use has also been documented with bacterial antigens. Mason et al. (1998) have designed and constructed a plant-optimized synthetic gene encoding the *Escherichia coli* heat-labile enterotoxin B subunit (LTB). Expression of LTB gene in potatoes increased antigen expression in leaves and tubers, and LTB molecules were assembled into native pentameric structures that were able to bind to their ganglioside receptors. When mice were fed with raw tuber slices they developed serum and fecal IgA anti-LTB antibodies, and were partially protected against challenge to orally delivered LT (Mason et al. 1998). This edible vaccine was also tested in human volunteers who received 50–100 g raw transgenic potato. Most of the participants (10 of 11 tested) developed serum anti-LTB antibodies (Tacket et al. 1998). Also transgenic potatoes engineered to synthesize CTB pentamers with affinity to G_{M1} gangliosides were immunogenic (inducing serum and intestinal CTB-specific antibodies) when fed to mice (Arakawa et al. 1998a). The serum samples neutralized the activity of CT on Vero cells and the immunized mice were partially protected (60 percent reduction in diarrheal fluid accumulation in the small intestine).

A plant-based multicomponent vaccine has been demonstrated to protect mice from enteric disease (Yu and Langridge 2001). This edible vaccine consisted of two CT fusion genes, one expressing a 22-amino acid immunodominant epitope of the murine rotavirus enterotoxin NSP4 to the CTB subunit (C-terminal fusion) and the other expressing the *E. coli* fimbrial colonization factor CFA/I to the CTA2 subunit (N-terminal fusion). When mice were fed with transgenic potato tuber tissues expressing the CT fusion proteins, antibody responses (serum IgG and intestinal IgG and IgA) against the NSP4, CTB, and CFA/I were detected. Cultured splenocytes from immune mice secreted IL-2 and IFN-γ, and diarrheal symptoms were reduced in severity and duration in passively immunized neonatal mice following rotavirus challenge.

FUTURE PROSPECTS AND CHALLENGES FOR THE DEVELOPMENT OF EDIBLE VACCINES

For almost a decade, research on the development of edible vaccines has focused on viral and bacterial antigens. These studies helped to establish the proof of the concept and the identification of appropriate methods for enhancing protein expression, as well as providing answers to fundamental questions such as the selection of an appropriate crop, the quantity of plant tissue constituting a vaccine dose, and the importance of structural integrity of expressed antigen. Moreover, human clinical trials have demonstrated that edible vaccines are safe and can induce systemic and mucosal immune responses without the aid of an adjuvant. Despite all these positive aspects, the immune responses elicited in this way are still modest and this remains one of the limiting factors for the development of an effective edible vaccine for human use. Furthermore, there is always the risk that induction of immunity after oral immunization may lead to inflammatory or allergic reactions as a result of the breakdown of the physiological tolerance toward food antigens.

By improving our understanding of the basic mechanisms involved in induction of immunity or tolerance, it

should be possible to manipulate the GALT. This will allow the preferential stimulation of protective systemic and mucosal immune responses against infectious pathogens or antigen-specific tolerance, which could be advantageous for treating autoimmune diseases or allergic disorders (Arakawa et al. 1998b). Furthermore, the determination of the molecular requirements for directing mucosally primed immunocompetent cells from the inductive sites to the effector sites will help in the design of more effective mucosal vaccines.

Nasal vaccines

Vaccines that can be administered via the nose appear to hold more promise than oral vaccines, because intranasal immunization generally requires a much lower dose of antigen, and elicits more potent immune responses (Table 2). There are several advantages to using the nose as a route of immunization and an intense search to develop safe and immunogenic nasal vaccines is currently under way:

- It is easily accessible.
- It is highly vascularized.
- The presence of numerous microvilli covering the nasal epithelium generates a large absorption surface.
- After intranasal immunization both systemic and mucosal immune responses are induced.
- Immune responses can be induced at distant mucosal sites.
- Its a noninvasive route and therefore it does not require needles and syringes.

After intranasal immunization, the balance between active immunity and tolerance would depend greatly on the nature of the antigen and its interaction with the NALT, as well as on the dose, adjuvant, frequency of antigen administration, and genetic background of the host (Kuper et al. 1992). Particulate antigens can be either removed by the mucociliary clearance system or sampled by M cells (which overlay the NALT); they are then transported to the posterior cervical lymph nodes (Kuper et al. 1992). In the case of soluble antigens, these molecules can penetrate the mucosal epithelium and reach the superficial cervical lymph nodes (Kuper et al. 1992). High doses of antigen administered intranasally are likely to reach the intestinal tract (Willoughby and Willoughby 1977) or be taken up directly by the posterior cervical lymph nodes instead of the superficial ones (Kuper et al. 1992). The superficial cervical lymph nodes, which drain the nasal mucosa, appear to be instrumental in the induction of mucosal tolerance (Kuper et al. 1992). Posterior cervical lymph nodes are involved in the generation of sIgA responses (Kuper et al. 1992). This suggests that the lymphocyte composition differs in different lymph nodes as a result of their 'homing' behavior, which underlies the observed divergence in the induction of either tolerance or immunity.

Table 2 *Differences between oral and nasal routes of immunization*

	Oral route	Nasal route
Proteolytic activity	High	Moderate
Distance to transport	Long	Small
Dose of antigen	High	Medium
Requirement of adjuvant	Yes	Yes
Antigen uptake	Poor	Good
Targeting requirement	Yes	Not necessary
Humoral responses	Low	High
Cellular responses	Low	High

VACCINE DELIVERY VIA THE NOSE

For the development of safer and better vaccines, much effort has been devoted to defining and producing protective antigens or epitopes from the pathogen of concern. When these antigens are given intranasally, they are weakly immunogenic or induce tolerance. To circumvent these problems, delivery systems and mucosal adjuvants have been developed:

- Use of replicating vectors expressing the antigen (live attenuated viruses or bacteria).
- Use of nonreplicating vectors (liposomes, microparticles, immune-stimulating complexes (ISCOM)).
- Use of recombinant plant viruses expressing antigens (cowpea mosaic virus).
- Use of cold-adapted influenza virus (FluMist vaccine).
- Antigen co-administered with an adjuvant (CT, LT, CpG, cytokines, etc.).
- Antigen adsorbed on bioadhesive polymers (chitosan, microparticles, etc.).

Vectors for delivering antigens via the nose

Replicating delivery systems present the antigen (protein or epitopes) in the context of a genetically modified live attenuated bacterium or virus, which provides a continuous antigenic stimulation and elicits broad humoral or cellular immune responses. It is important that these vectors express adequate amounts of antigen, have a tropism for the mucosal epithelium, and do not revert to the virulent form. As vectored vaccines are live, they are likely to share the same antigen-processing and presentation pathway as the pathogen, and therefore elicit the desired type of immune responses. Among the recombinant vectors that have been widely tested are: *Mycobacterium bovis* (Langermann et al. 1994), *Vibrio cholerae* (Chen et al. 1998), *E. coli* (Turner et al. 2001), *Shigella flexneri* (Anderson et al. 2000), *Salmonella typhi* (Galen et al. 1997), vaccinia virus (Bernstein 2000), adenovirus

(Gallichan and Rosenthal 1996), and poliovirus (Crotty et al. 1999). However, for live attenuated microorganisms, the induction of immunity to the organism used as a carrier could preclude their use for booster immunizations, and reversion to virulence may be a potential problem. As an alternative, plant viruses, which are not infectious to mammals, have been tested with antigenic peptides (Dalsgaard et al. 1997; Durrani et al. 1998; Olszewska and Steward 2001), and commensal lactobacilli (*Lactobacillus plantarum*) have begun to receive attention as safe noninvasive vectors (Shaw et al. 2000).

The intranasal delivery of vaccines using nonreplicating vectors has the advantage that it eliminates one of the major concerns, that of reversion to virulence. For successful intranasal immunization, the nonreplicating vector should: (1) protect the antigen from degradation; (2) allow its transport via the M cells; and (3) promote the appropriate type of immune responses required for protection. Among the various nonreplicating vector systems, particles such as liposomes (Mader et al. 2000), virosomes (Cusi et al. 2000), ISCOMs (Hu et al. 2001), biodegradable microparticles (Vajdy and O'Hagan 2001), biovector systems (Von Hoegen 2001), and proteosomes (Levi et al. 1995) have been extensively studied. The availability of so many different formulations allows the selection of the most appropriate to address the clinical needs, the nature of the antigen, and the type of desired immune responses. However, for some of these vectors there are certain limitations for human use, e.g. toxicity is a major drawback of using ISCOMs as a vaccine delivery system. This is because of the presence of saponins that have strong hemolytic and cytolytic activity even at low doses. For biodegradable microparticles, there are several concerns about the stability of the entrapped antigen during storage, the efficacy of microparticle uptake by the mucosal epithelium, and problems in the production of sterile preparations for human use.

An alternate approach to encapsulation is to adsorb antigens on to the surface of biodegradable polymeric lamellar substrate particles (PLSP). This is a simple procedure that avoids pH changes caused by bulk polymer degradation and the use of solvents and, therefore, should be less damaging to the vaccine. Several antigens such as proteins, peptides, and viral particles have been adsorbed on to PLSPs and tested for immunogenicity after nasal administration (Jabbal-Gill et al. 2001), e.g. adsorbed influenza vaccine induced strong secretory and systemic antibody responses (Jabbal-Gill et al. 2000). Carbohydrate biopolymers have also been tested for their ability to enhance the immunogenicity of adsorbed antigens. In particular, chitosan, which is a cationic polysaccharide and binds strongly to negatively charged cell surfaces and mucus, greatly improves the absorption of antigens from the nasal cavity and augments antigen-specific immune responses (Bacon et al. 2000; Illum et al. 2001).

Adjuvants for intranasal immunization

Administration of antigens via the nose has the potential to induce a wide range of immune responses; the types of response induced in this way can be significantly influenced by the use of adjuvants. In experimental animal models, the most potent mucosal adjuvants are CT and LT. Both are strong mucosal immunogens in their own right and can act as effective adjuvants to intranasally co-administered antigens by enhancing serum and secretory antibody responses and cytotoxic T-cell responses (Imaoka et al. 1988; Rappuoli et al. 1999; Kurono et al. 1999; Partidos et al. 1999). As their enzymatic activity precludes their use in humans, much effort has been devoted to attempting to dissociate their adjuvant properties from their toxicity. Using site-directed mutagenesis, several mutants have been generated with significantly reduced ADP-ribosylating activity and toxicity compared with the holotoxin (Rappuoli et al. 1999; Pizza et al. 2001). These molecules have been shown to exert adjuvant activity to co-administered antigens by increasing serum and secretory antibody responses (Pizza et al. 2001), modulating immune responses as a consequence of their ADP-ribosylating activity (Ryan et al. 2000), and potentiating CTL responses (Partidos et al. 1996). However, there are several concerns about the role of G_{M1}-binding molecules that target neuronal tissues in mucosal immunity. Intranasal delivery of CT targets the main olfactory nerves and epithelium, which is directly connected with the olfactory bulbs, and raises the possibility of the induction of neuronal damage (Van Ginkel et al. 2000). Furthermore, it has been suggested that the use of CT as intranasal adjuvant results in the redirection of vaccine proteins into the CNS (Van Ginkel et al. 2000). However, recent studies in mice have shown that LT mutants are safe and that they do not induce any detectable inflammatory response in any anatomical site (Peppoloni et al. 2003).

Bacterial DNA has potent immunostimulatory properties caused by the presence of unmethylated CpG motifs, which are far more common in bacterial than in vertebrate DNA (Krieg 2002). A similar immunostimulatory effect can be seen with synthetic ODNs containing CpG motifs (ODN-CpG) (Roman et al. 1997). In studies where vaccine antigens were co-delivered with an ODN-CpG via the mucosal routes, strong systemic and mucosal immune responses were detected (McCluskie et al. 2001a). Furthermore, in some instances protective immune responses were enhanced, as demonstrated in mice immunized intranasally with an ODN-CpG and a recombinant glycoprotein of HSV1 (Gallichan et al. 2001) or with an influenza virus peptide representing a mimic of the antigenic site A of hemagglutinin (Partidos et al. 2001). CpG motifs can also modulate the adjuvant effect of CT or mutants of LT when they are co-administered with recombinant proteins or peptides, promoting a Th1-type immune responses (Olszewska

et al. 2000; McCluskie et al. 2001b). Therefore, CpG-ODNs are novel mucosal adjuvants, which either alone or in combination with other adjuvants can modulate and enhance humoral and cellular immunity.

An alternate approach to the potentiation of immune responses to intranasally administered antigens is to use cytokines as adjuvants. The cytokine microenvironment at the site of antigen delivery plays a critical role in the induction and regulation of immune responses. Boyaka et al. (1999) and Boyaka and McGhee (2001) have demonstrated that intranasally delivered IL-6 and IL-12 can enhance antigen-specific serum antibody responses to co-administered protein antigen, but only IL-12 is able to trigger antigen-specific secretory IgA responses. Also it has been reported that IL-1α and IL-1β exhibit mucosal adjuvant activity for the induction of serum IgG and mucosal IgA antibody responses when they are nasally co-administered with soluble protein antigens (Staats and Ennis 1999). In addition, it was found that the combination of IL-1α + IL-18, IL-1α + IL-12, and IL-1α + IL-12 + GM-CSF each induced optimal splenocyte anti-HIV CTL responses in mice immunized intranasally (Staats et al. 2001). Despite the mucosal adjuvanticity of certain cytokines it should be noted that they are pleotropic molecules and, therefore, they have complex effects that depend on the state of activation of different immunocompetent cells and the balance of other cytokines.

CONCLUDING REMARKS

This is an exciting time in the field of vaccinology. Thanks to the technological advances in biomedical sciences we now have a wide range of new immunization strategies and vaccine delivery options. More importantly, the widespread administration of vaccines without the use of needles is now a distinct possibility and this is a significant advantage for immunization programs in less developed countries, because such administration would be simple, painless, and economical.

An intranasal vaccine against influenza virus (NasalFlu, containing inactivated virus and LT as an adjuvant) has already been approved in Switzerland. In addition, another influenza vaccine – the FluMist, a live cold-adapted virus – has been developed for delivery in the form of a spray and is close to being licensed for human use. It is certain that more 'needle-free' vaccines will follow.

New vaccine technologies

JAMES P. NATARO AND MYRON M. LEVINE

Transcutaneous immunization	1	Live attenuated vector vaccines	5
Virosomes	2	Prime-boost immunization	10
Proteosomes	3	Conclusions	11
Virus-like particles	4	References	11

Immunization/vaccination remains the most efficient intervention against infectious diseases. However, for many infections the traditional approaches have not yielded safe, effective, convenient or affordable vaccines. For these applications and in the interest of safer and more practical interventions for diseases already covered by traditional vaccines, there remains a need for improved vaccine technologies. In this chapter, we summarize some of the most promising vaccine delivery technologies and evaluate their future promise.

TRANSCUTANEOUS IMMUNIZATION

Transcutaneous immunization (TCI) is the direct application of antigen and adjuvant to intact or slightly abraded skin. Once through the skin, an antigen encounters a dense population of efficient antigen-presenting cells (APC), the Langerhans' cells, which trigger innate and adaptive immune responses to antigens surmounting the integument (Hammond et al. 2001a). The potential advantages of TCI are many. Foremost is the ease of vaccine administration, avoiding the expense, logistics, and risk of needle-based injection. TCI is presumably safer than other parenteral routes, although information about this is still preliminary.

Successful TCI requires delivery of the immunogen through the stratum corneum (SC), the skin's principal barrier to the passage of molecules (Scharton-Kersten et al. 1999). Several strategies have been devised to permit facile penetration of the SC by molecular immunogens. Simple hydration results in significant, but transient, changes in the SC, and may be sufficient to allow penetration of some immunogens (Kaiserlian and Etchart 1999).

Preclinical experience with TCI appears very promising, and has illuminated several prerequisites of this approach. Foremost among these is the need for adjuvant co-administration to enhance immune responsiveness. The adjuvants most frequently employed are the cholera enterotoxin (CT) and the related *E. coli* heat-labile toxin (LT) (Glenn et al. 1998, 1999; Scharton-Kersten et al. 2000; Chen et al. 2002; John et al. 2002; Yu et al. 2002), although other adjuvants may also be effective (Scharton-Kersten et al. 2000). The mixture of CT or LT with tetanus toxoid dramatically increases antibody responses when compared with the administration of the antigens alone (Hammond et al. 2001b). Mice immunized with diphtheria toxoid (DTx) and CT developed excellent immune responses which persisted for over 9 months. Using tetanus toxoid as a model antigen, Hammond et al. (2001b) found that TCI induced both T-helper (Th) 1 and 2 (Th1 and Th2) responses (with a Th2 bias) partly dependent on choice of adjuvant. Several studies have also suggested that TCI can elicit mucosal immune responses (John et al. 2002; Yu et al. 2002) as well as cell-mediated responses (Yu et al. 2002). John et al. (2002) found that TCI of mice with CT resulted in mucosal responses similar to those engendered by a live attenuated cholera vaccine administered orally.

The adjuvant-dependent immunogenicity of a TCI vaccine was demonstrated in volunteers receiving CS6 colonization factor of enterotoxigenic *E. coli* (ETEC). Participants received patches containing 250, 500, 1000, or 2000 μg CS6 alone or with 500 μg LT, dosed at 0, 1, and 3 months (Guerena-Burgueno et al. 2002). In the absence of LT, there were no demonstrable immune

responses to the CS6 antigen. In contrast, when CS6 was given with LT, 68 percent and 53 percent had anti-CS6 IgG and IgA, respectively, and 100 percent and 90 percent had anti-LT IgG and IgA, respectively. Fourteen (74 percent) of 19 volunteers developed mild delayed-type hypersensitivity (DTH) skin reactions after the second or third dose; no other adverse events were reported.

Questions that remain to be answered about TCI include the precision of dosing, as well as efficacy and safety in infants and young children, whose skin may be more porous than adults and in whom hypersensitivity may be a concern. In addition, the efficacy of LT/CT as an adjuvant may be limited in immune populations, perhaps precluding its use more than once (see

New approaches to vaccine delivery for further discussion of this aspect of vaccinology).

VIROSOMES

Liposomes, vesicles comprised of membrane-type phospholipids, can act as effective adjuvants for protein antigens that are incorporated into the vesicle membrane (Gregoriadis and Allison 1974; Allison and Gregoriadis 1976, 1990; Tan and Gregoriadis 1990) (Figure 1). Liposomes are efficiently taken up by APCs and their contents are processed largely via major histocompatibility complex (MHC) class II-dependent pathways. Liposome uptake can be further facilitated in a number of ways. Coating liposomes with antibodies, for example, can target them to Fcγ receptors on APCs. Liposomes produced by reconstitution of viral glycoproteins and lipids (virosomes) have many of the properties of the parent viruses. Virosomes have been adapted as delivery vehicles for antigens, antigen DNA, drugs, proteins, and water-soluble materials (Bron et al. 1993, 1994).

Virosomes initiate an immune response by binding and fusing with the eukaryotic plasma membrane, thereby discharging their cargo into the cytoplasm. As would therefore be predicted, antigens are chiefly presented in the context of MHC-I molecules. Effective $CD8^+$ cytotoxic T-cell (CTL) responses to virosome-encapsulated antigens are reported (Gregoriadis and Allison 1974; Gregoriadis 1990; Nerome et al. 1990; Miller et al. 1992; Arkema et al. 2000; Gluck et al. 2000). Bungener et al. (2002a, 2002b) have shown that membrane fusion-active virosomes, but not fusion-inactive virosomes, are able to deliver a test antigen to dendritic cells for MHC-I presentation; fusion activity of virosomes was not required for MHC-II presentation of the same antigen. Mucosal application of virosomes can elicit systemic and secretory IgA (sIgA) responses (Cusi et al. 2000, 2002).

Virosome-based influenza vaccines

Influenza virosomes are prepared by detergent purification of influenza surface glycoproteins and reconstitution with a mixture of phosphatidylcholine (70 percent), phosphatidylethanolamine (20 percent), and influenza virus envelope phospholipids (10 percent). This mixture was carefully chosen: egg yolk phosphatidylcholine has an excellent safety record of administration to humans; phosphatidylethanolamine has been shown to stimulate B cells to secrete antibody in the absence of T-cell help (Garcon and Six 1991); and the influenza virus glycoproteins haemagglutinin (HA) and neuraminidase (NA) play key roles in virosome function. HA is the major fusion-promoting protein of the virosome, and also directly mediates binding to APCs.

The influenza virosome vaccine has been tested in humans of all ages and appears to be safe and immunogenic when administered intranasally (Kaji et al. 1992;

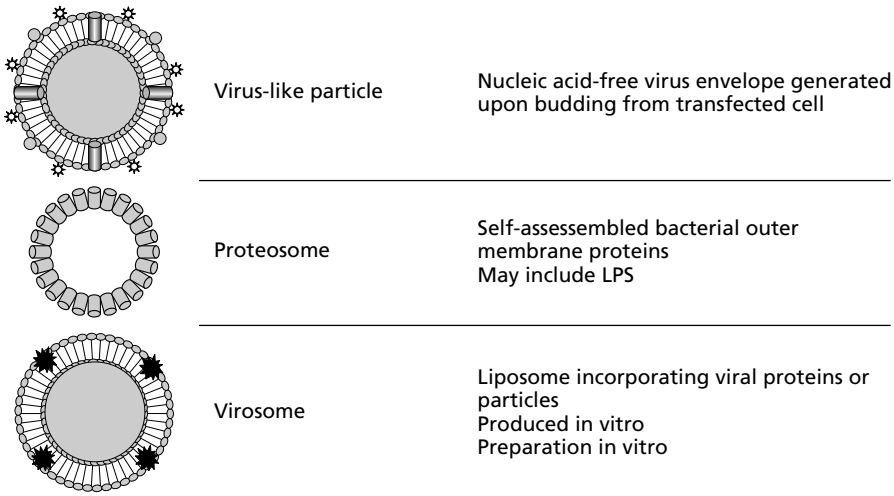

Figure 1 *Virus-like particles, proteosomes, and virosomes are artificial, membrane-bound bodies that are used to deliver antigens to the immune system.*

Gluck et al. 1994, 2000; Conne et al. 1997; Schaad et al. 2000; Herzog et al. 2002). Following the excellent performance of the influenza prototype and the natural versatility of the virosome approach, antigens from other viruses have been incorporated into influenza virosomes. These notably include the F antigen from respiratory syncytial virus (Cusi et al. 2002), the protective core peptide of hepatitis C virus (Hunziker et al. 2002), and the hepatitis A virus vaccine, considered in greater detail below.

Hepatitis virosome vaccines

The first breakthrough in the use of virosomes for delivery of foreign antigen was the generation of a hepatitis A vaccine comprising hepatitis A virus (HAV) strain RG-SB integrated into influenza-derived virosomal particles (Loutan et al. 1994). In phase 3 clinical studies, seroconversion was documented in more than 98 percent of volunteers within 4 weeks of immunization (Argentini et al. 1995; Gluck et al. 1992). Booster injections of the virosomal vaccine 12 months after the initial dose resulted in 100 percent seroconversion, increasing anti-HAV antibody titers by 11- to 40-fold (Loutan et al. 1994).

The nature of virosomes makes them particularly amenable to the integration and presentation of multiple antigens. Hepatitis B surface antigen (HBsAg) has been successfully integrated into HAV-containing virosomes (Mengiardi et al. 1995). In further steps, the diphtheria toxoid, the α-tetanus toxoid, the β-tetanus toxoid, and the inactivated hepatitis A virion were additionally crosslinked to the virosome surface (Gluck 1995). Several such combination vaccines are licensed in Europe and Asia.

Other virosome applications

As virosomes efficiently fuse their contents with the cell cytoplasm, virosomes may be effective vectors for nucleic acid vaccine delivery (Cusi and Gluck 2000; Cusi 2001). They may also increase the uptake of antisense oligonucleotides (ODN), considered as promising therapeutic agents against viral diseases and cancer, or as immunomodulators.

Virosomes were used to deliver synthetic peptide-based malaria vaccine SPf66 (Poltl-Frank et al. 1999). Immunization of mice with two intramuscular doses of the virosome vaccine engendered higher antibody titers to the malaria antigen than when the antigen was administered with alum. An HIV vaccine, based on genetically modified glycoprotein and nonstructural peptides, is also under development (Kaneda 2000).

PROTEOSOMES

The proteosome nomenclature emphasizes the distinctive physical and biological properties of preparations of the outer membrane proteins (OMP) of gram-negative bacteria (Lowell et al. 1988a, 1988b). As membrane proteins, OMPs are highly hydrophobic; when isolated by detergent extraction, hydrophobic protein–protein interactions cause them to self-assemble into multimolecular particles with morphological characteristics of vesicles up to several hundred nanometers in diameter. The typical method of creating a proteosome-based vaccine is to process a mixture of detergent-solubilized OMPs with amphiphilic antigens, in a manner that facilitates noncovalent association of the antigens with the proteins and excludes the detergent (Wetzler et al. 1989, 1992; Wetzler 1994). Proteosomes therefore comprise noncovalent complexes of bacterial OMPs studded with amphiphilic antigen. A nasal proteosome influenza vaccine constructed in this way is currently in clinical trials. A second approach to deriving proteosome vaccines is to formulate a mixture of vaccine antigen with a soluble pre-formed proteosome adjuvant preparation made up of proteosome particles complexed with lipopolysaccharide (LPS). This system (termed 'IVX-908') may either incorporate amphiphilic or entirely hydrophilic molecules, or result from mixing of antigens with the pre-formed LPS-solubilized proteosome particles. IVX-908 possesses immunostimulatory properties in part resulting from its LPS. A proteosome shigella LPS vaccine has been shown to be promising in phase 1 and 2 clinical trials (see below) (Fries et al. 2001).

Proteosome vaccine particles exhibit certain characteristics that improve their safety and immunogenicity. Their surface hydrophobicity may improve uptake and processing by APCs, in particular promoting Th1-type responses. It has also been suggested that the immunogenicity of proteosomes is improved by the interaction of bacterial OMPs (Massari et al. 2002) and LPS (Chow et al. 1999) with the Toll-like receptors (TLR) of APCs. Although interaction with TLRs could cause some concern with inflammatory side effects, experience with the gram-negative OMPs (from *Neisseria meningitidis*) serving as carriers in *Haemophilus influenzae* vaccines has been positive (Heath 1998).

FluINsure, the nasal proteosome-based vaccine for influenza under development by ID Biomedical Corp., has undergone extensive clinical testing, with generally positive results (Plante et al. 2001). Phase 1 or 2 clinical trials of FluINsure using single-dose (15, 30, or 45 μg HA) and two-dose (7.5, 15, or 30 μg HA per dose) regimens in a total of 330 healthy adults have documented a high degree of safety and tolerance, in the presence of serum IgG responses similar to intramuscular vaccines (Treanor et al. 2001; Halperin et al. 2002). In addition, FluINsure recipients exhibited rises in sIgA titers to levels thought to be protective against influenza infection (Plante et al. 2001).

The proteosome shigella vaccine candidate comprises LPS and OMPs of *Shigella sonnei* and *S. flexneri* 2a (Fries et al. 2001). In dose-escalating phase 1 and 2 clinical

studies, 111 healthy adults received two intranasal doses of the vaccine 2 weeks apart (Fries et al. 2001; McKenzie et al. 2001). Adverse effects were limited to mild nasal congestion and rhinorrhea in half to two-thirds of vaccinees. More than 90 percent of vaccinees demonstrated significant antibody-secreting cell responses (ASC); 60–90 percent responded with serum antibodies (four-fold geometric mean titer or GMT increases in IgG and IgA were typical at 1-mg doses).

In a challenge study using live *S. flexneri* given less than 48 days after immunization, vaccine efficacy was 36 percent against any diarrhea ($p = 0.04$), 78 percent against fever ($p = 0.003$), and 56 percent against severe symptoms including dysentery ($p = 0.03$) (Durbin et al. 2001). Although this vaccine appears to be well tolerated and fairly immunogenic, the brief duration of immune response after two doses limits its appeal. Nevertheless, the vaccine provides an interesting proof of principle that could be improved on in further iterations of this strategy. The most practical target for intranasal proteosome vaccines is likely to be respiratory viruses, for which a brief period of protection during the peak season would be beneficial. Parenterally administered proteosome vaccines could have broader application, but require additional clinical development.

VIRUS-LIKE PARTICLES

Virus-like particles (VLP) are nonreplicating, recombinant, viral capsids, with a structure similar to that of the virions from which they are derived. VLPs are formed by self-assembly of viral structural protein(s) on synthesis in eukaryotic or prokaryotic expression systems; they therefore present the native conformation of viral antigens but lack viral nucleic acid (Kruger et al. 1999). VLPs are particularly useful when native virions cannot be readily isolated or produced or when a very high degree of vaccine safety is desired (e.g. immunization of immunocompromised patients). They may be made up of single viral capsid proteins (e.g. papillomavirus and hepatitis B core protein) or multiple proteins contributing to a more complex structure (e.g. herpesviruses, rotavirus, and Ebola virus).

The immune response to VLPs is typically balanced to include neutralizing antibodies and cytotoxic T-cell responses, presumably as a result of the presentation of multiple native antigens in each particle (Sedlik et al. 1997, 1999, 2000). The balance of systemic vs mucosal immune responses is determined by the route of administration, as well as by the antigenic characteristics of the VLP itself. Papillomavirus VLPs have been shown to induce strong peripheral IgG responses on parenteral administration, and good sIgA responses when given by the oral route (Gerber et al. 2001). Unlike many other new vaccine delivery approaches, immunogenicity is strong without the need for an additional adjuvant (see below). However, although cytotoxic (Sedlik et al. 1997) and Th1 responses (Lo-Man et al. 1998) are typically robust on VLP administration, responses can be further augmented or modified by co-administration of adjuvant (Siadat-Pajouh and Cai 2001), often approaching that derived from native viral infection.

Manufacture of VLPs has been made possible only by the advent of molecular biotechnology. The fundamental approach entails the cloning of genes encoding viral capsid proteins into a mammalian expression vector or other expression system. Among the many systems successfully adapted are baculovirus (Garnier et al. 1995), *Pichia pastoris* (yeast cells) (Sasnauskas et al. 1999), plant systems (e.g. *Nicotiana*) (O'Brien et al. 2000), and bacterial expression systems (Chen et al. 2001). The expression vector and host cell system typically must be optimized. On protein expression, some VLPs bud from the plasma membrane and self-assemble, whereas others must be post-translationally modified or otherwise manipulated.

The versatility of the VLP approach has proved to be formidable. A partial list of vaccines in various stages of testing include those against rotavirus (O'Neal et al. 1998; Jiang et al. 1999; Coste et al. 2000, 2001; Siadat-Pajouh and Cai 2001), Norwalk virus (Ball et al. 1999), parvovirus (Sedlik et al. 1997, 1999), hepatitis viruses (Li et al. 1997; Lorenzo et al. 2001), papillomavirus (Pumpens et al. 2002; Schiller and Lowy 2001b), calicivirus (Nagesha et al. 1999), HIV (Garnier et al. 1995; Weber et al. 1995; Peters et al. 1997), hantavirus (Koletzki et al. 2000), polyoma virus (Goldmann et al. 1999), and influenza virus (Latham and Galarza 2001; Watanabe et al. 2002).

Some VLPs have progressed to phase 1 or 2 clinical trials (Ball et al. 1999; Zhang et al. 2000; Evans et al. 2001; Schiller and Lowy 2001a). In nearly all such studies, VLPs have fulfilled their promise in providing an excellent safety profile, coupled with good immunogenicity. Evans et al. (2001) reported on a phase 1 study of VLPs comprising the L1 protein of human papilloma viruses (HPV). The vaccine was well tolerated and induced high levels of both binding and neutralizing antibodies. The vaccine induced strong B- and T-cell responses, and T-helper epitopes appear to be conserved across HPV types. Harro et al. (2001) reported the results of a double-masked, placebo-controlled, dose-escalation trial to evaluate the safety and immunogenicity of an HPV type 16 (HPV16) L1 VLP vaccine in healthy adults. Volunteers were given intramuscular injections with placebo or with 10- or 50-μg doses of HPV16 L1 VLP vaccine without adjuvant, or with alum or MF59 as adjuvants at 0, 1, and 4 months. All vaccine formulations were well tolerated, and all participants receiving vaccine seroconverted. With the higher dose, most of the recipients achieved serum antibody titers that were approximately 40-fold higher than what is observed in natural infection. Zhang et al. (2000) administered multiple doses of HPV VLPs (HPV6b) without

adjuvant to 33 participants with genital warts. All subjects mounted DTH responses to the vaccine. Complete regression of genital warts was observed in 25 of 33 evaluable participants over the 20-week observation period. The vaccine was well tolerated.

Ball et al. (1999) have conducted trials of a Norwalk virus (NV) VLP made up of a single capsid protein. Twenty adults received two doses of vaccine 3 weeks apart. No side effects were observed or reported by the volunteers. All vaccinees given the highest dose responded with fourfold or more increases in serum IgG antibody titers. Most of the volunteers (83 percent; 15 of 18) responded after the first rNV VLP dose and showed no increase in serum IgG antibody titer after the second dose. Tacket et al. (2003) fed Norwalk VLPs without adjuvant to 36 healthy adult volunteers at doses of 250 μg (n = 10), 500 μg (n = 10), and 2000 μg (n = 10); six volunteers received a single dose of placebo. Of those who received 250 μg 90 percent developed rises in serum anti-VLP IgG antibodies. Higher doses did not produce higher responses. All vaccinees developed significant rises in IgA anti-VLP ASCs, although only 30–40 percent of volunteers developed mucosal anti-VLP IgA antibodies. Lymphoproliferative responses and interferon γ (IFN-γ) production were observed transiently among those who received 250 μg or 500 μg, but not 2000 μg of VLP.

Peters et al. (1997) reported the results of a phase 2 study of the yeast-derived VLP HIV vaccine Ty.p24.VLP (p24-VLP), in HIV-antibody-positive asymptomatic volunteers. Fifteen volunteers, with p24 antibody titers >1/100, p24 antigen <20 pg/l, and CD4 $>350 \times 10^9$/l, were enrolled. Five were immunized with aluminum hydroxide placebo, five with 25 μg, and five with 100 μg p24-VLP in alum adjuvant at weeks 0 and 4 by the intramuscular route. No serious adverse events were observed in any of the groups, although efficacy data have not been provided.

VLPs represent a highly versatile strategy for vaccine delivery. Human trials have thus far borne out the safety and immunogenicity of this immunization strategy, although no VLP vaccine has yet been licensed. One important question about this class of vaccines is the duration and breadth of protection, and the possible requirement for adjuvant has not yet been determined for mucosally administered VLP vaccines.

LIVE ATTENUATED VECTOR VACCINES

The use of attenuated bacterial strains as mucosal live vectors to deliver antigens of unrelated pathogens is a highly promising vaccine strategy for several reasons (Medina and Guzman 2001):

- The mucosal route of administration efficiently induces both systemic and local protective immunity, which is favorable for pathogens and toxins that enter through mucosal surfaces.
- Mucosal delivery is usually associated with low reactogenicity.
- Logistics of vaccine administration are typically easier for mucosal vaccines, especially in the context of mass immunization campaigns.
- As they are perceived as less invasive than parenteral vaccines, oral vaccines have a generally high level of public acceptance and increased compliance.
- Genetic engineering strategies used to construct mucosal vaccines confer a high degree of versatility. Live attenuated enteric vaccines would be expected to have relatively low manufacturing costs compared with many other vaccines.

Live attenuated salmonella vaccines

Attenuated *Salmonella enterica* serovar Typhi vaccines were among the first oral bacterial vaccines, and they remain among the most promising. The great promise of *S. typhi* as a live attenuated vaccine derives from its pathogenic strategy (Kingsley and Baumler 2000; Santos et al. 2003; Zhang et al. 2003). *S. typhi* briefly colonizes the small intestinal mucosa, and invades at the level of the Peyer's patch epithelium (Figure 2). On entry into the lymphoid follicles, the organisms are taken up into macrophages, which transport the bacteria throughout the body. Attenuation strategies have been devised that permit the organism to enter the lymphoid tissue but not to persist or circulate via the bloodstream. This modified pathway is ideal for presentation of antigens to the gut-associated lymphoid tissue.

Germanier and Fuer (1975) derived the first attenuated *S. typhi* vaccine (designated Ty21a) by nonspecific chemical mutagenesis of parent strain Ty2. Ty21a harbors a galactose epimerase mutation, does not express the Vi (virulence) capsular polysaccharide, and exhibits many additional mutations that collectively contribute to its attenuation. Although Ty21a has served as a safe and effective typhoid fever vaccine for more than a decade, it has certain shortcomings, chief among these being the requirement for multiple doses to achieve protective efficacy (Levine et al. 1990). The advent of genetic engineering provides an opportunity to exploit specific attenuation strategies, because this organism is genetically tractable.

Several groups have prepared recombinant *S. typhi* vaccine candidates and tested them in phase 1 studies in human volunteers. Four strains proved to be sufficiently well tolerated and immunogenic to stimulate interest in additional clinical trials. These include: Ty800 (attenuated by virtue of mutation in the two-component regulatory system PhoPQ) (Hohmann et al. 1996), χ4372 (inactivated in the CRP transcriptional regulator) (Tacket et al. 1992a), CVD 908-*htrA* (inactivated in aromatic biosynthesis pathway and production of a stress protease) (Tacket et al. 2000b), and ZH9 (inactivated in

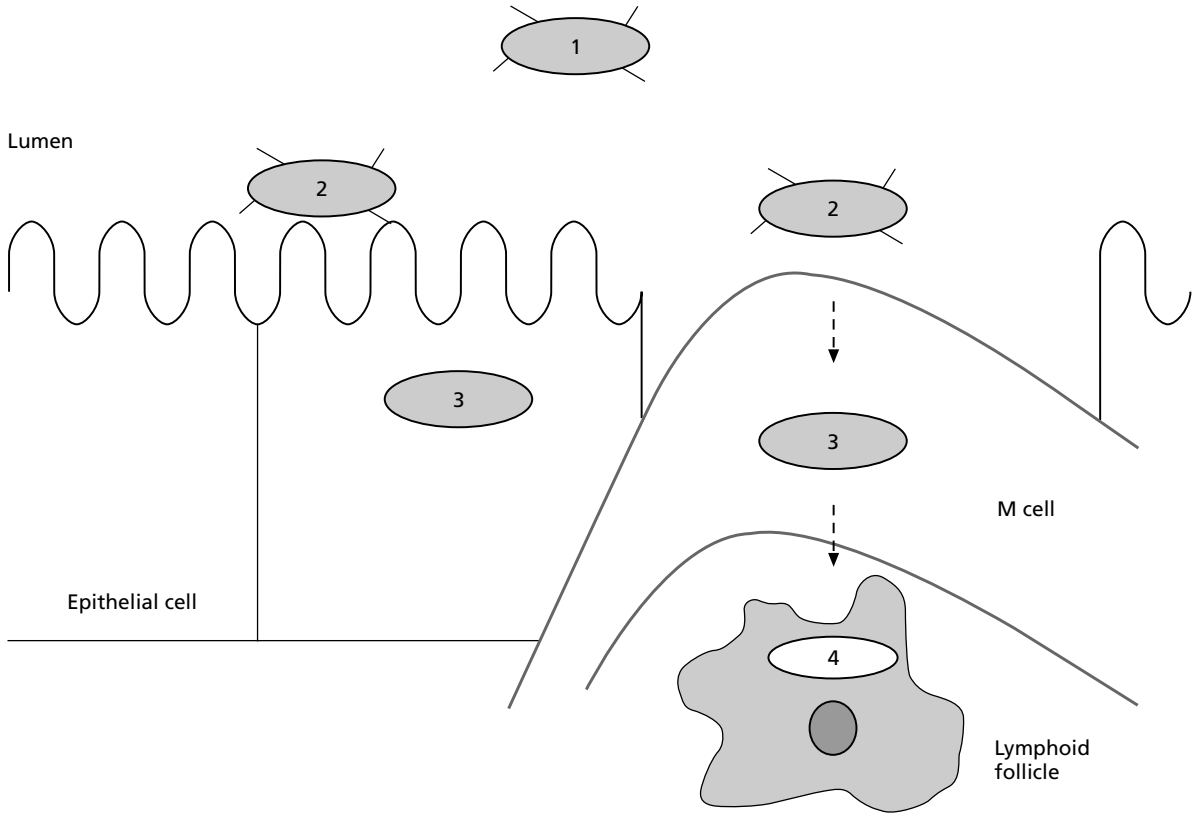

Figure 2 *Microanatomical locations of live attenuated vaccine vectors. Nonliving vaccines remain in the lumen of the gastrointestinal tract (1) and can be sampled passively by the gut-associated lymphoid tissue. Some live vaccine vectors, e.g. those derived from* Vibrio cholerae*, actively adhere to the surface of the absorptive epithelium (2) or to the M cells overlying the lymphoid follicles. Invasive bacterial vectors, e.g. strains of* Shigella *and* Listeria *spp., invade the epithelial cells but remain in the cytoplasm (3), whereas vectors such as* Salmonella *translocate through the epithelial layer and access the underlying antigen-presenting cells (4). The focus of live attenuated vector technology is to construct mutants that target the immunogen to one or more of these compartments.*

the aromatic biosynthesis pathway and the salmonella pathogenicity island-2 type III secretion system secreton) (Hindle et al. 2002; Khan et al. 2003).

The immediate predecessor of CVD 908-*htrA* was CVD 908 (Hone et al. 1991), attenuated by virtue of two nonreverting deletion mutations within the chromosomal *aroC* and *aroD* genes. These two genes encode enzymes critical in the biosynthetic pathway leading to synthesis of chorismate, the key precursor required for synthesis of the aromatic amino acids (Hoiseth and Stocker 1981); chorismate is further required for the synthesis of *p*-aminobenzoic acid, which is ultimately converted to the purine nucleotides ATP and GTP. Although immunization of volunteers with CVD 908 is well tolerated and highly immunogenic (Tacket et al. 1992a, p. 216), a silent vaccinemia was detected in 100 percent of volunteers who ingested 5×10^8 colony-forming units (cfu), wherein vaccine organisms were recovered from blood cultures collected between days 4 and 8 after immunization (Levine et al. 1996, 1997). This silent bacteremia was not associated with adverse clinical symptoms and was self-limiting. Nevertheless, further attenuation to obviate vaccinemias was pursued.

CVD 908 was attenuated further by a defined deletion mutation in the *htrA* gene, which encodes a heat shock-induced serine protease responsible for degradation of misfolded periplasmic proteins (Pallen and Wren 1997). As predicted, CVD 908-*htrA* was well tolerated at doses up to 5×10^9 without vaccinemia (Tacket et al. 1997). Volunteers ingesting CVD 908-*htrA* manifested a broad immune response to *S. typhi* antigens, including intestinal sIgA antibodies, serum IgG antibodies, and cellular immune responses.

The versatility of *S. typhi* as a vector to deliver foreign antigens has been demonstrated in both CVD 908 and CVD 908-*htrA* backgrounds. Volunteers receiving two doses of *S. typhi* CVD 908 expressing the *Plasmodium falciparum* circumsporozoite protein (CSP) developed cytotoxic T lymphocytes (CTL) to CSP-transfected target cells (Gonzalez et al. 1994). In a second study, 21 healthy adult volunteers received a single dose of CVD 908-*htrA*-carrying, plasmid-encoded, tetanus toxin fragment C under the control of one or two different promoters induced in vivo (*nirB* and *lpp*) (Tacket et al. 2000a). Neither vaccine induced fever or vaccinemia. Of three seronegative volunteers who received 10^9 cfu CVD

908-*htrA* (pTET*lpp*), a single oral dose of the live vector expressing fragment C seroconverted one of the three and elicited a rise in serum tetanus anti-toxin 43 times above the protective level.

McKenzie et al. (2002) fed CVD 908-*htrA*-expressing *Helicobacter pylori* urease to healthy volunteers at doses up to about 5×10^9 cfu; the vaccine was well tolerated and induced urease-specific IgA and IgG ASCs in 25 percent and 88 percent of the immunized individuals.

With the establishment of the ability of *S. typhi* to deliver foreign antigens, attention has turned to improving the technical aspects of heterologous gene expression (Galen and Levine 2001). Accordingly, genetic tools have been developed to express heterologous antigens from strong in vivo-induced promoters (see above); assure recombinant plasmid replication in the absence of antibiotic selection (Galen et al. 1999); and enable secretion of foreign antigens to the extracellular milieu. With experience and expertise accumulating rapidly, the future of *Salmonella* spp. as a live attenuated vector vaccine appears bright.

Live attenuated shigella vaccines

Similar to *Salmonella*, shigella strains invade the intestinal mucosa and enter the gut-associated lymphoid tissue. Unlike *Salmonella*, *Shigella* spp. are not adapted for long-term persistence in macrophages, and bacteremias are rare. *Shigella* spp. therefore offer some advantages and some disadvantages to use as a live vector. Similar to *Salmonella*, advances in the understanding of shigella pathogenesis allow precise disruption of virulence genes without alteration in the invasive phenotype, which is believed to be required for a protective response. Recently identified attenuating strategies are finally yielding vaccine candidate strains that are immunogenic in humans, yet are well tolerated clinically.

Sansonetti and co-workers (1991) constructed a series of *Shigella flexneri* 5a strains with mutations in the *virG* (*icsA*) gene, which is involved in cell-to-cell spread (Bernardini et al. 1989) but which is not required for invasiveness. Additional mutations were constructed in *ompB* or *iuc*, the latter encoding the siderophore aerobactin (Sansonetti et al. 1991). In animal studies, the *ompB/virG* strain was well tolerated but not fully protective against shigella challenge. In contrast, the *virG*/*iuc* strain caused mild adverse effects in some animals, but 100 percent protection after challenge (Sansonetti and Arondel 1989). Similarly, a *S. flexneri* 2a strain with the *virG* and *iuc* mutations (SC602) caused symptoms of mild shigellosis in healthy adult volunteers at doses of 10^6 and 10^8 cfu, whereas a dose of 10^4 caused only mild symptoms in a few volunteers (Coster et al. 1999). Importantly, volunteers ingesting a single dose of 10^4 SC602 were protected against challenge with wild-type *S. flexneri* 2a. This experience underscores the dose-related relationship between immune response and reactogenicity; however, doses tolerated by healthy adults may not be so for children or other more vulnerable hosts, and thus a higher level of safety is desirable.

A *virG*-deleted strain of *S. sonnei*, strain WRSS1, has been evaluated in a phase 1 clinical study. A single dose of 10^3, 10^4, 10^5, or 10^6 cfu caused low-grade fever or mild diarrhea in 22 percent of recipients (Kotloff et al. 2002). However, the vaccine was highly immunogenic, generating impressive levels of serum anti-shigella LPS and anti-LPS IgA ASCs (Kotloff et al. 2002).

Work at the CVD has yielded similar experience. Noriega and co-workers (1994) generated *S. flexneri* 2a vaccine candidate CVD 1203, with mutations in *aroA* and *virG*. A single dose of 10^6 CVD 1203 was well tolerated and immunogenic. However, at doses of 10^8 or 10^9 cfu, short-lived adverse reactions, including fever, diarrhea, and/or mild dysentery, were observed (Kotloff et al. 1996). This experience again illustrates the dose-dependent nature of adverse effects and calls for a higher degree of safety in attenuated shigella constructs.

In progress toward achieving the correct balance of immunogenicity and safety, Noriega and co-workers (1994) generate *S. flexneri* 2a strain CVD 1204, harboring a deletion in the *guaBA* operon (Anderson et al. 2000). This mutation, which renders the bacteria auxotrophic for guanine, is more attenuating and virtually nonreactogenic in the guinea-pig model of keratoconjunctivitis. Two further derivatives of CVD 1204 were constructed: CVD 1208 carries additional mutations in the genes encoding shigella enterotoxins 1 and 2 (ShET1 and ShET2, encoded by *set* and *sen*, respectively), and CVD 1207, which harbors a deletion in *virG* in addition to the mutations in *guaBA*, *set*, and *sen* (Kotloff et al. 2000; Levine 2000). Human studies on this series of candidates are under way. Both CVD 1207 and CVD 1208 have proved to be well tolerated but the latter appears to be more immunogenic (Kotloff et al. 2000).

Live attenuated *Vibrio cholerae* vaccines

Vibrio cholerae has many attributes that make it an attractive vaccine delivery vehicle. It is a noninvasive organism which colonizes the human intestinal mucosa and induces potent, long-lived mucosal and systemic humoral responses (Kaper et al. 1995). The lack of invasiveness of *V. cholerae* reduces the likelihood of systemic reactions and theoretically reduces the need for global attenuation of the pathogen. *V. cholerae* has been intensively studied at the molecular level and is genetically tractable.

Several live attenuated *V. cholerae* vaccine constructs are safe and immunogenic in humans (Sack and Albert 1994; Liu et al. 1995; Cohen 1997; Herzog et al. 1997;

Tacket et al. 1999; Yamamoto 2000). CVD 103HgR (*ctxA*−, *hly*−, *recA*, classic Inaba strain 569B) is the first recombinant live attenuated cholera vaccine, and it continues to set the standard for safety and efficacy for cholera vaccines (Levine et al. 1988; Migasena et al. 1989; Cryz et al. 1990; Kotloff et al. 1992; Su-Arehawaratana et al. 1992; Tacket et al. 1992b, 1999; Gotuzzo et al. 1993; Simanjuntak et al. 1993; Sack and Albert 1994; Lagos et al. 1995; Losonsky et al. 1997; Perry et al. 1998; Yamamoto 2000). The organism is principally attenuated via deletion of the CTA subunit, but its parent strain also shows a mild defect in its ability to colonize the human intestine (Levine et al. 1988). CVD 103-HgR has been administered to more than 6000 individuals in placebo-controlled phase 1 and 2 trials, including infants and HIV-infected individuals (Levine et al. 1988; Migasena et al. 1989; Cryz et al. 1990, 1992; Kotloff et al. 1992; Su-Arehawaratana et al. 1992; Suharyono et al. 1992; Tacket et al. 1992b, 1999; Gotuzzo et al. 1993; Losonsky et al. 1993, 1997; Simanjuntak et al. 1993; Lagos et al. 1995, 1999a, b; Perry et al. 1998; Taylor et al. 1999; Richie et al. 2000). In all studies, neither diarrhea nor any other adverse reaction occurred significantly more often in vaccinees than in placebo recipients. CVD 103HgR conferred strong protective immunity in North American volunteers against experimental challenge with wild-type *V. cholerae* strains. In one study, a single dose conferred 100 percent protection against experimental challenge with a toxigenic classic strain when volunteers were challenged only 8 days after immunization; protective immunity was also documented to extend to at least 6 months after immunization, the longest interval tested (Tacket et al. 1992b). In a randomized, double-masked, placebo-controlled, multicenter trial, a single dose of this strain conferred 91 percent protective efficacy against moderate or severe diarrhea after challenge with toxigenic El Tor *V. cholerae* (Tacket et al. 1999). The ability of CVD 103-HgR to provide long-term protection against natural challenge in cholera-endemic countries has not been established. Over 4 years of surveillance during a field trial in Indonesia, only 14 percent efficacy was observed overall (Richie et al. 2000). During the first 6 months of this trial (when protection might be expected to b maximal), few cases of cholera occurred. However, during a post-licensure intervention with CVD 103-HgR carried out under the auspices of the World Health Organization during a cholera outbreak in Micronesia, it was calculated that the vaccine provided 79 percent effectiveness in preventing cholera (Claire-Lise Chaignat, WHO, personal communication). In view of its consistent efficacy in multiple experimental challenge studies in conferring a high level of protection in North American volunteers against both classic and El Tor cholera caused by either Inaba or Ogawa serotypes, and its ability to elicit strong vibriocidal antibody responses, CVD 103-HgR has been licensed in many countries (including Canada, Australia, and Switzerland).

Several other attenuated cholera vaccines have been tested in humans (Levine et al. 1988; Taylor et al. 1994; Kaper et al. 1995; Liu et al. 1995; Sack et al. 1997; Benitez et al. 1999; Valle et al. 2000). A series of nonmotile cholera variants is well tolerated and immunogenic in healthy adults and is undergoing further clinical trials (Taylor et al. 1994).

V. cholerae vector strains have been used to deliver heterologous antigens (Butterton et al. 1995) such as *Shigella sonnei* LPS (Favre et al. 1996), *E. coli* Shiga toxin B subunit (Acheson et al. 1996), enterohemorrhagic *E. coli* intimin (Butterton et al. 1997), tetanus toxin fragment C (Chen et al. 1998), *B. pertussis* tracheal colonization factor (Chen et al. 1998), *Entamoeba histolytica* surface protein (Ryan et al. 1997b), and *Clostridium difficile* toxin A (Ryan et al. 1997a).

BCG-based vector vaccines

The currently licensed bacille Calmette–Guérin (BCG) vaccine is a multiply passaged *Mycobacterium bovis* strain, originally developed in 1908 (Fine 1989). The bacterium is highly attenuated and acceptably safe, but it is only partially protective against tuberculous disease, principally the extrapulmonary forms (Fine 2001). By virtue of its derivation from *M. bovis* and its history of multiple passage, BCG is lacking 16 discrete regions of the *M. tuberculosis* genome. There is therefore no risk of reversion to virulent *M. tuberculosis*. The efficacy of BCG varies among countries, and indeed the BCG vaccines used throughout the world display substantial genetic diversity attributed to its handling over the course of the twentieth century (Fine 1995, 2001; Behr and Small 1997, 1999; Behr et al. 1999; Fine and Vynnycky 1998).

Similar to mycobacteria that naturally infect humans, BCG is taken up into macrophage and dendritic cells and undergo limited replication within the phagolysosome (Inaba et al. 1993). As expected, therefore, BCG presents antigens predominantly in the context of MHC-II (Kaufmann and Ladel 1994; Kaufmann et al. 1995; Ladel et al. 1995a, b); BCG elicits predominantly a CD4-mediated Th1-type response. However, modifications of the route, timing, and dose of administration can elicit more balanced Th1/Th2 immunity (Bretscher 1992, 1994; Power et al. 1998).

BCG has been considered as a vector for delivery of antigens when a Th1 response is desired. As *Listeria monocytogenes* is an intracellular pathogen normally controlled by Th1 responses, several investigators have adapted BCG for use in listeria vaccine development (Hess et al. 1998; Conradt et al. 1999). Hess and colleagues expressed the p60 protective antigen of *L. monocytogenes* in various cellular compartments of the BCG bacterium (Hess 2002). Not unexpectedly, surface

display or secretion of p60 provided the strongest responses. The market for a human listeria vaccine is doubtful, but progress in a BCG-derived listeria vaccine development may constitute an important proof of principle.

BCG-derived vaccine candidates have been constructed against various pathogens, including bacteria (e.g. *Borrelia burgdorferi* (Langermann et al. 1994a), *Bordetella pertussis* (Nascimento et al. 2000), and *Streptococcus pneumoniae* (Langermann et al. 1994b; Miyaji et al. 2001)); parasites (*Leishmania* (Connell et al. 1993; Abdelhak et al. 1995) and *Schistosoma* (Kremer et al. 1996)); and viral pathogens (HIV (Aldovini and Young 1990, 1991) and papillomavirus (Jabbar et al. 2000)). Edelman et al. (1999) at the University of Maryland tested a recombinant BCG (rBCG) vaccine expressing the outer surface protein A (OspA) of *B. burgdorferi*. Before human studies, the vaccine had proven highly immunogenic and protective in mice (Stover et al. 1993). Twenty-four adults received one intradermal injection of the rBCG-OspA vaccine containing escalating vaccine doses ranging from 2×10^4 to 2×10^7 cfu (Edelman et al. 1999). Local ulceration was the most common adverse effect; however, 83 percent of recipients of the highest dose developed BCG-positive draining lesions at the immunization site, persisting for up to 70 days (Figure 3). Despite these reactions, none of the volunteers at any dose manifested detectable post-immunization OspA antibody titers, although over half of vaccine recipients developed positive purified protein derivative (PPD) responses. These data illustrate the limitations of BCG as a vaccine vector, including limited antibody responses; more importantly, however, the threat of persistent shedding of BCG from cutaneous sites would constitute a potential risk to immunocompromised contacts.

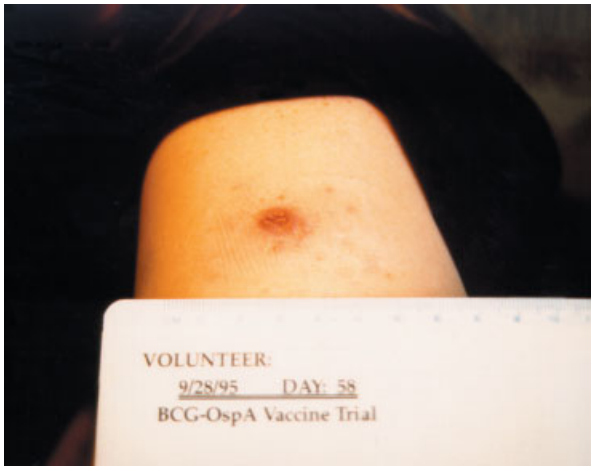

Figure 3 *Eschar caused by recombinant BCG vaccine. Large ulcerating eschar on the arm of a patient receiving one dose of BCG–outer surface protein A (OspA) vaccine 58 days previously. (Courtesy of R. Edelman, University of Maryland Center for Vaccine Development.)*

Live attenuated listeria vaccines

As a prototypical intracellular pathogen amenable to genetic manipulation, *L. monocytogenes* has been proposed as a vaccine vector against infections controlled by CTL and CD8 responses. *L. monocytogenes* pursues a pathogenic strategy similar to that of *Shigella*, in which the organism is engulfed by the eukaryotic cell, lyses the phagosome, and takes up residence in the cytoplasm (Portnoy et al. 2002). From this privileged site, the bacterium is protected from antibody responses, but can be eradicated by strong, cell-mediated, IFN-γ-driven responses (Portnoy et al. 1989; Finelli et al. 1999; Kerksiek and Pamer 1999; O'Riordan et al. 2002).

L. monocytogenes has been exploited for MHC-I presentation of a large number of viral, parasite, and tumor antigens, in either protein or nucleic acid form (Schafer et al. 1992; Dietrich et al. 2000, 2002; Gentschev et al. 2000, 2001, 2002; Spreng et al. 2000). Several of these constructs have proved to be safe and effective vaccines in mouse models (Ikonomidis et al. 1994; Ochsenbein et al. 1999; Dietrich et al. 2002; Soussi et al. 2002). However, as *L. monocytogenes* is a human pathogen, there is justified concern over possible adverse effects, especially in immunocompromised vaccinees. Friedman et al. (2000) have constructed a highly attenuated strain of *L. monocytogenes* that requires D-alanine, which is not available in human tissues. These investigators engineered the bacteria to express the HIV-1 Gag protein, and showed that the recombinant vaccine was as efficient at stimulating Gag-specific human CTLs in vitro as wild-type recombinants. This vaccine is considered to be a candidate for human trials and could serve as an important test case for *Listeria*-based vaccine strategies.

Other vector vaccines

Several other bacteria have been advanced as vector vaccines. Among these are several commensals, which imply a high degree of safety. Medaglini and colleagues (1995) engineered *Streptococcus gordonii*, a normal inhabitant of the human mouth, to express antigens of the M protein of *S. pyogenes*. In preparation for clinical trials of the vectored vaccine, K.L. Kotloff (personal communication) and co-workers evaluated the ability to implant the carrier strain (*S. gordonii*) resistant to streptomycin and 5-fluoro-2-deoxyuridine) into the nose and mouth of volunteers, and then delineated the time to eradication, both spontaneous and antibiotic induced. Inoculation was generally well tolerated. Symptoms reported most often within 4 days of inoculation were stuffy nose (36 percent), headache (30 percent), and sore throat (19 percent). The strain was detected by culture in the mouths of 97 percent of participants. A 5-day

course of azithromycin eliminated the strain in all participants. Without antibiotics, 82 percent spontaneously eradicated the implanted strain within 1 week, and all cleared by 1 month. Results of these studies will be used to design future phase I trials to evaluate a *S. gordonii* live vector vaccine expressing, on its surface, the conserved region of *S. pyogenes* M protein.

PRIME-BOOST IMMUNIZATION

Despite the success of vaccine technologies against a plethora of infectious diseases, certain infections have resisted vaccine strategies. Chief among these are HIV, malaria, and to a large extent tuberculosis. These infections have in common a requirement for strong cell-mediated responses, which are difficult to generate using traditional parenteral vaccine delivery strategies. In response to this problem, various innovative strategies have been devised, including some already discussed in this chapter. An additional, highly innovative immunization approach comprises a multiple-dose schedule in which the initial dose(s) prime the immune response, and subsequent doses deliver the same target antigens in the context of a different delivery vehicle, thereby engendering strong responses. This strategy, termed 'heterologous prime boost', has led to vigorous cell-mediated responses not as yet achieved by any other approach.

One of the earliest illustrations of the value of prime boost for generation of protective cell-mediated immunity (CMI) responses was provided by Li and coworkers in 1993. These investigators constructed a recombinant influenza virus expressing a CD8 T-cell epitope from the CSP of *Plasmodium yoelii*. Immunization of mice with the recombinant influenza virus, followed by a recombinant vaccinia virus expressing the entire CSP, induced protective immunity against a live sporozoite challenge. However, immunization with recombinant vaccinia virus first, followed by a booster injection with recombinant influenza virus, failed to induce protection. Subsequent to this promising start, several other groups corroborated the findings in malaria using several different heterologous prime-boost regimens (Hill et al. 2000; Bruna-Romero et al. 2001; Jones et al. 2001; Rogers et al. 2001; Schneider et al. 2001), and the utility of this approach for malaria immunization is being hotly pursued.

Also, in 1993, two separate groups reported highly promising results employing a heterologous prime-boost approach to HIV immunization. Graham et al. (1993) inoculated 12 volunteers with recombinant vaccinia virus expressing HIV gp160 glycoprotein, and then boosted them with recombinant gp160 protein. After booster immunization, the sera of all vaccinees showed strong antibody responses detected by western blot and enzyme-linked immunosorbent assay (ELISA); five blocked binding of CD4 cells to gp120. The prime-boost strategy was more immunogenic than either product alone. The same month, Cooney et al. (1993) independently reported the results of a similar phase 1 study in which 13 participants immunized with recombinant vaccinia virus expressing gp160 were boosted with recombinant gp160. T cell and antibody responses detected after immunization with either vaccine alone were of low magnitude and transient. In contrast, recipients of the combination regimen developed higher, more prolonged, T-cell proliferative responses to gp160.

Since these pioneering studies, the power of the prime-boost phenomenon in HIV immunization has been extended to other targets as well. Evans et al. (1999) have shown that a canarypox vaccine expressing multiple HIV antigens yielded stronger responses in volunteers when accompanied by injection of recombinant gp120. An interesting twist to this study was that the gp120 inoculation produced the same boost when administered simultaneously with the canarypox vaccine.

A great deal of attention has surrounded the phenomenon of priming with a nucleic acid vaccine, followed by parenteral boost with the protein antigen, usually delivered in a viral vector. Kent et al. (1998) evaluated a consecutive immunization strategy in mice involving priming with DNA and boosting with recombinant fowlpox virus vaccines, each encoding Gag and Pol HIV-1 antigens. The heterologous prime-boost approach induced greater HIV-1-specific immunity than either vaccine given alone; mice given the prime-boost regimen were protected from challenge with a recombinant vaccinia virus expressing HIV-1 antigens. In a subsequent experiment using rhesus macaques, a dramatic boosting effect on DNA vaccine-primed HIV-1-specific helper and cytotoxic T-lymphocyte responses was observed, although accompanied by a decline in HIV-1 antibody titers. The prime-boost regimen protected macaques from an intravenous HIV-1 challenge.

Robinson et al. (1999, 2000) compared eight different immunization protocols for their abilities to induce responses to nonpathogenic immunodeficiency virus challenge in rhesus macaque monkeys. The best containment response was induced by a regimen comprising intradermal DNA priming followed by fowlpox virus booster immunization; responses were characterized by strong T-cell responses which were over ten-fold higher than homologous prime-boost regimens. These investigators subsequently delivered Gag, Pol, and Env antigens in the context of two DNA injections (intramuscular or intradermal) given 8 weeks apart. They then boosted the monkeys with the same proteins expressed in the vaccinia virus Ankara vector (MVA), given intramuscularly and intradermally at 24 weeks. This regimen elicited high levels of antigen-specific T cells, of both CD4 and CD8 type. The monkeys were protected from intrarectal viral challenge with the highly pathogenic simian–human immunodeficiency virus 89.6P given 7 months after immunization. Curiously, however, these

investigators were later to show that two doses of the MVA vaccine, without DNA vaccine boost, were able to induce significant protection.

Since the initial success with prime boost in malaria and HIV vaccine efforts, this approach has been extended to other vaccines. In sum, this is substantial evidence that mucosal priming followed by parenteral boosting yields augmented, and broadened, immune responses, including TH1, TH2, and SIGA components. The concept of enteral prime/parenteral boost was first suggested by human studies using oral polio vaccine (OPV) and parenteral inactivated polio vaccine (IPV) recipients, boosted with either OPV or IPV (Herremans et al. 1999). In this study, parenteral IPV immunization boosted systemic and mucosal IgA antibody responses in previously OPV-immunized patients, but not in IPV-immunized individuals. Interestingly, IPV immunization of OPV-primed patients, although immunized decades earlier, mounted rapid (by day 7) and vigorous IgG as well as IgA responses in the periphery as well as at the mucosal level. IPV boosting of OPV-primed individuals resulted in broader immune responses which were at least as vigorous in all aspects as those seen in individuals primed and boosted with the parenteral vaccine.

These human data have subsequently been reproduced in mouse models. Using the pertactin protein of *Bordetella pertussis* expressed cytoplasmically in an attenuated salmonella vector, Anderson et al. (1996) demonstrated that effective boosting can occur in the setting of very weak responses to the initial prime (i.e. the mucosa may be primed without exhibiting demonstrable antibody response). Neither mice immunized with pertactin alone nor those immunized just with two doses of recombinant *S. typhimurium* pertactin exhibited anamnestic responses. The investigators also measured anti-pertactin IgG subclasses and found that mice immunized orally with *S. typhimurium* pertactin and boosted with 10 μg purified antigen produced IgG2a and IgG2b, whereas purified pertactin alone induced primarily IgG1. Splenic T-cell proliferation was observed in mice immunized orally with *S. typhimurium* pertactin and boosted with only 0.1 μg pertactin, thus demonstrating not only antibody but also T-cell priming by *S. typhimurium* pertactin. Interestingly, the 0.1 μg parenteral boosting dose of pertactin did not generate an immune response in the absence of priming. Ward et al. (1999) have documented similar findings using *S. typhimurium* expressing the C-terminal domain of *Clostridium difficile* toxin A (cytoplasmically). Using *Salmonella*-expressing antigens from *Streptococcus mutans* (Jespersgaard et al. 2001) and *Helicobacter pylori* (Londono-Arcila et al. 2002), other investigators have demonstrated that mucosal prime/parenteral boost results in boosting of systemic responses with good TH1/TH2 balance and boosting of SIGA. The limitations of enteral prime-parenteral boost are yet to be fully delineated, although the data generated thus far suggest that this is a very promising approach to the development of a strong, balanced response to protein antigens.

The immunological basis of the prime-boost phenomenon remains incompletely understood. The priming antigen apparently induces the maturation of antigen-specific T and B cells, some of which will persist and circulate widely as memory cells when the antigen is no longer present. These memory cells will rapidly expand on re-exposure to the same antigen, even if the antigen is given at a site very distant from the initial exposure. The mechanism behind the apparent synergy of prime-boost responses is harder to explain. One hypothesis states that, as prime-boost presents the dominant epitopes in different backgrounds, the immune response is spared the 'noise' of a large array of low-affinity epitopes. This focused response may be optimally vigorous. A second hypothesis suggests that the heterologous prime-boost approach avoids a secondary response to the vector, which some feel may be inhibitory to maximal antigen-specific boosting. Complete understanding of this phenomenon will be a significant contribution to future vaccine development strategies.

CONCLUSIONS

The science of vaccinology has produced some of the most important breakthroughs in the history of medicine. Yet despite our ability to control and even eradicate infections using immunization, limitations and weaknesses remain. Among these are infections so far recalcitrant to immunization strategies, our inability to engender the most appropriate class of immune response, and the need for ever-increasing levels of vaccine safety. In this chapter, we have highlighted just a few of the many new applications of biotechnology to address these problems. These and many other technologies offer hope in providing economically feasible barriers to control some of our most dangerous enemies.

T- and B-cell epitopes	1	Final comments: difficulties and misconceptions	28
Peptide vaccines based on B-cell epitopes	1	Acknowledgments	28
Candidate peptide vaccines against BCEs	16	References	29

INTRODUCTION

For several decades synthetic peptides have been extremely valuable tools for dissecting the immune response to complex antigens and pathogens on an epitope level. Peptides as antigens have been extensively reviewed (Van Regenmortel and Muller 1999). Vaccines based on synthetic peptides or defined epitopes have met considerable interest and high expectations. A large number of vaccines have been tested in clinical trials and even more in animal models, but so far none has been licensed. This chapter is an attempt to present the current status of the vast field of experimental or candidate vaccines based on synthetic peptides. Much of what can be said about peptide vaccines applies also to other epitope-based strategies, but these are beyond the scope of this review. We acknowledge that such a review can never be complete and is necessarily biased toward the authors' experience – or the lack of it.

T- AND B-CELL EPITOPES

Sequence and post-translational modifications provide a protein with a unique three-dimensional surface architecture, which is the basis of cognate interactions with its molecular partners. The unique surface structure is exploited by the immune system to recognize antigens and to discriminate between self and nonself. Complementary domains, epitopes, and paratopes of antigens and antibodies are the minimal cognate structures (Jerne 1960), and the basis of the primordial intelligence that drives the teleological choices of the immune system, first at the induction stage and again at the effector stage of the immune response (Muller 2001b). T and B cells recognize epitopes and antigens in fundamentally different ways. Although B cells bind to intact antigens, T cells recognize only processed antigens presented as peptides by molecules of the major histocompatibility complex (MHC) of antigen presenting cells. Over the past years, both T-cell epitopes (TCE) and B-cell epitopes (BCE) have been identified in most antigens. Peptides have been used as minimal surrogate antigens to induce a prophylactic or therapeutic T- and/or B-cell response against pathogens, tumors, and other diseases.

PEPTIDE VACCINES BASED ON B-CELL EPITOPES

Conformational and sequential BCEs

The antibody paratope recognizes the congruent and complementary epitope of the antigen in its native, unprocessed, three-dimensional conformation. Complementary features of epitope and paratope converge to form relatively flat, bumpy surfaces of several square nanometers in size covering only a fraction of the solvent accessible surface of the antigen. Seminal radiological studies with hen egg lysozyme revealed, for instance, that 16 residues interact with 17 amino acids of

a monoclonal antibody (reviewed by Bentley 1996). When analyzed by amino acid replacement techniques, antibody binding appears to be mediated by a smaller set of well-defined 'contact' residues plus additional weaker interactions, which are usually more difficult to define but add to the affinity of binding. Mutation of a critical contact residue may abrogate antibody binding, and allow a pathogen to escape neutralization. Usually such contact residues are on distant sequence domains, brought together by protein folding to form conformational, discontinuous, or assembled epitopes. Most neutralizing and protective BCEs are conformational antigenic sites. Occasionally most elements of an epitope are contributed by amino acid residues, which are all within a short stretch of sequence. These continuous, segmental, linear, or sequential epitopes, in contrast to conformational epitopes, can be operationally defined by their ability to be mimicked by synthetic peptides of the same sequence. Despite sometimes-complex conformations such as helices, β sheets, or loops, these can be mimicked by sequence-homologous synthetic peptides (Table 1).

Identification of sequential BCEs

C- and N-terminal ends of proteins are frequently surface exposed. As a result of lower structural constraints, termini tend to be more flexible and are more easily mimicked by peptides. Peptides of many antigenic N- or C-terminal epitopes have been used to obtain antibodies against proteins. In some cases the N-terminus carried a protective epitope (Langeveld et al. 1994a). Loops protruding from the antigen surface and surface-accessible helices are also frequent targets of antibodies and sometimes they can be mimicked by short synthetic peptides. In the absence of structural data, the prediction of sequential epitopes is guesswork. Among the numerous strategies that have been utilized to identify *protective* sequential BCEs (Morris 1996), the most straightforward is to screen overlapping peptides covering the whole sequence or at least predicted surface-exposed domains with protective monoclonal antibodies (mAb) by pepscan, multispin assays, or SPOT assays. Larger (e.g. recombinant, tryptic, or other) fragments or peptide libraries (e.g. synthetic or phage displayed) and polyclonal antibodies can serve as second-rate alternatives to define sequential epitopes. Substitution analogs of synthetic peptides (e.g. alanine scan) combined with mAbs are powerful tools to identify contact residues of sequential epitopes. As a result of the many degrees of rotational freedom, the conformation of most peptides is ill-defined. For these reasons, only a limited number of neutralizing or protective sequential epitopes have been identified for some pathogens and none for others (Table 1).

Mimotopes mimic conformational BCEs

Conformational epitopes are even more difficult to mimic with small synthetic molecules, referred to as mimotopes. Mimotopes may have no sequence homology with the protein, but the spatial arrangement of their residues provides an array of atoms that resembles those contacted by the paratope in the protein epitope. Among a variety of approaches the most powerful are based on synthetic peptide libraries or (random) peptide libraries expressed by phages. Peptides as mimotopes have been used as surrogate antigens of experimental vaccines against proteins (Steward 2001) and even carbohydrates (reviewed by Monzavi-Karbassi et al. 2002). Many (antigenic) mimotopes that react with (preformed) antibodies have been described, but only a fraction of them also induced antibodies that crossreacted in vivo. When peptide mimotopes are used for immunization, usually few of the highly antigenic peptides induce virus-crossreactive antibodies, reflecting a severe disparity among antigenicity, immunogenicity, and crossreactive immunogenicity (El Kasmi et al. 1999b) with or without neutralizing or protective activity (reviewed by Deroo and Muller 2001) (Table 2).
Steward and colleagues (Steward et al. 1995; Olszewska et al. 2000) described a remarkable peptide mimotope, which was selected against an mAb of the measles virus fusion protein. Although the mAb did not neutralize the virus in vitro, the mimotope induced antibodies, which protected in a rodent model against a viral challenge. In another study, the same group described a peptide mimotope selected with a combinatorial solid-phase peptide library against a protective mAb of the fusion protein of the respiratory syncytial virus. These mimotopes, presented as multiple antigenic peptides (MAP), induced antibodies, which neutralized the virus in vitro, and reduced the virus load in immunized mice to 1 percent (Chargelegue et al. 1997, 1998).

Peptide vaccines based on BCEs: general features

THE BEGINNING

Chemical synthesis of peptides was developed during the 1960s (Marglin and Merrifield 1970), and thanks to numerous technological advances peptides became increasingly popular in immunology. In 1963, Anderer and colleagues showed for the first time that a C-terminal peptide of the coat protein of tobacco mosaic virus induced virus-neutralizing antibodies. More than 10 years later, Langbeheim et al. (1976) inactivated a bacteriophage by immunizing with a synthetic polymer of its coat protein made of 20 peptides. In the early 1980s protective immunity in the host animal was obtained with a peptide corresponding to the GH loop of the VP1 capsid protein of food-and-mouth disease

(DiMarchi et al. 1986). These early studies encouraged many authors to explore immunization strategies based on sequential BCE and synthetic peptides. Peptides corresponding to neutralizing epitopes have been identified in a number of surface proteins of viruses, bacteria, and parasites (see Table 1). However, after the initial enthusiasm, it became clear that peptides are far from being ideal antigens. Our own experience taught us that it is a long way from the identification of a neutralizing linear epitope to a protective vaccine (Ziegler et al. 1996; Putz et al. 2004).

CHEMICALLY DEFINED VACCINES

A major advantage of chemically synthesized peptides in comparison to biological products is at the level of production, quality, and safety. Peptides are relatively simple to synthesize in large quantities. They are chemically fully defined, and can be obtained with high purity and minimal batch variations. They are thermostable and have long shelf-lives at room temperature. They do not require cold chains, which are expensive and difficult to maintain in developing countries. In comparison to recombinant products, peptides do not require complex fermenting and downstream-processing capacity. Unlike live vectors, peptides have no infectious potential. Containment requirements are minimal in comparison to those for the production of large quantities of infectious microorganisms. There is no risk of reversion of attenuation.

CONFORMATIONAL STABILITY

Most neutralizing and protective BCEs are conformational and difficult to mimic with linear peptides (see earlier section 'Mimotopes mimic conformational BCEs'). In the case of a sequential epitope, linear peptides may miss some structural features of the native epitope involved in antibody interaction. Furthermore, peptides are highly flexible structures, presenting to the

B-cell repertoire a multitude of different conformations, only some of which may resemble the native epitope and induce antibodies crossreacting with the parent protein (crossreactive immunogenicity).

To overcome problems with peptide flexibility, different strategies have been explored including constraining peptides by chemical or peptidic scaffolds (Valero et al. 2000; Hudecz 2001), e.g. the M protein of the group A streptococci (GAS) contains a sequential epitope targeted by opsonizing and protective antibodies (reviewed by Olive et al. 2004). However, synthetic peptides representing this epitope alone did not display the helical structure of the native protein. Only when flanked by irrelevant yeast-derived GCN4 sequences did the epitope peptide fold into the helical structure and induce protective antibodies (Relf et al. 1996; Hayman et al. 1997). Such strategies reduce conformational diversity but structural similarity may suffer. A poor balance between conformational constraints and conformational similarity of the peptide with the native protein critically determines crossreactive immunogenicity.

IMMUNOGENICITY

Live-attenuated viruses induce a strong immune response, protecting sometimes for decades after a single injection without the need of adjuvants. Recombinant proteins formulated with adjuvants protect after several boosts for 5–10 years. In comparison, synthetic peptides have a weak inherent immunogenicity; normally they are much less immunogenic than their parent proteins even after repeated injections with relatively high doses. They depend on potent adjuvants (Van Regenmortel and Muller 1999), which are not licensed for human use. Most experimental vaccines have been tested by invasive routes using a variety of formulations, adjuvants, and cytokines (see Table 1). Adjuvants have been reviewed by Del Giudice and Rappuoli (see Adjuvants and subunit vaccines). The low immunogenicity, combined with conformational diversity of a peptide antigen, are the major obstacles to the induction of high levels of crossreactive or neutralizing antibodies.

ENZYMATIC DEGRADATION IN VIVO

In vivo, peptides are rapidly degraded by proteases further limiting their immunogenicity. To overcome this drawback numerous attempts have been made to develop more stable peptide derivatives using non-natural amino acids (Chorev and Goodman 1995; Briand et al. 1997; Nargi et al. 1999), analogs with modified peptide bonds (pseudopeptides) (Bianco 1999) and other so-called peptidomimetics (Benkirane et al. 1996a; Stemmer et al. 1999), e.g. a retro-inverso peptide induced protective antibodies against foot-and-mouth disease (Briand et al. 1997) and a pseudopeptide inhibited experimental allergic encephalitis (Jameson et al. 1994).

Requirement for TCEs

A CHOICE OF HELPER TCE

To be immunogenic in the context of a natural population, the BCEs must be combined with a peptide containing a potent T-helper cell epitope, which can be presented by most MHC class II haplotypes or an immunogenic carrier protein. Broadly, MHC II-reactive TCEs have been proposed for this purpose (Table 3), including non-natural pan-DR-binding peptides, engineered to bind to a wide range of DR molecules (Panina-Bordignon et al. 1989; Alexander et al. 1994, 1998). The carrier proteins most frequently used in experimental conjugate vaccines include tetanus toxoid (TT), diphtheria toxoid (DT), keyhole limpet hemocyanin, ovalbumin (OVA), and bovine serum albumin

(BSA). TT and DT, two highly immunogenic carriers both licensed for human use, have been successfully utilized in experimental peptide conjugate vaccines (Muller et al. 1982; Herrington et al. 1987; Putz et al. 2004). Despite difficulties to obtain efficient loading and homogeneous conjugates, this technology is commonly used in licensed polysaccharide conjugate vaccines against bacteria. Coupling the BCE to a TCE or carrier protein, however, undermines some advantages of peptides including chemical purity, homogeneity, and stability.

DESIGN OF PEPTIDES CONTAINING BOTH T- AND B-CELL EPITOPES

Although in some cases simple mixing of a TCE peptide with a BCE peptide has given satisfactory results (Partidos et al. 1992a; Brons et al. 1996), covalent coupling is generally believed to be required. Co-linear synthesis of the BCE with a peptide containing a (promiscuous) TCE is one option (Partidos et al. 1991). Although the technology to produce peptides of increasing length has made considerable progress (reviewed by Demotz et al. 2001), yield, purity, and production costs are likely to limit peptide length. The longer the peptide, the less competitive the chemical synthesis will be in comparison to production of recombinants.

The need for a conjugated TCE adds several levels of complexity to the design of peptide vaccines: the antigenic peptide may be conjugated C or N terminally to one or several TCE peptides (or a carrier protein). Orientation, number, and structural propensity of the TCE critically determine the conformation of the BCE, and crossreactive immunogenicity with the native protein as well as neutralizing activity of antibodies (Dyrberg and Oldstone 1986; Lipkin et al. 1988; Lu et al. 1991; Partidos et al. 1992b, c; Fernandez et al. 1993; Sharma et al. 1993; El Kasmi et al. 1998, 2000). Although some permutational T–B constructs produced low levels of antibodies without crossreactivity, others containing the same BCE framed differently with the same TCE, or flanked in the same way with different TCE, induced crossreactive antibodies. Although inactive and cross-neutralizing antibody-inducing constructs can be very similar, iterative optimization can be tedious (El Kasmi et al. 1999a). Systematic studies seem to suggest that TCE–TCE–BCE ('TTB') constructs may be the most efficient (Obeid et al. 1995; El Kasmi et al. 1999a). The orientation of co-linear peptides may also influence the immunogenicity of the TCE by activating T cells against neoepitopes which have no resemblance to pathogen-specific TCEs. TCEs and BCEs may also be combined using different chemical conjugation strategies including the formation of thioesters (Defoort et al. 1992b), oxime bonds (Rose 1994), disulfide bonds (Drijfhout and Bloemhoff 1991), thioether bonds (Schnolzer and Kent 1992), thiazolidine bonds (Rao and Tam 1994), and others (Spetzler and Tam 1995; Purcell et al. 2003; reviewed by Jackson et al. 2002). These coupling chemistries differed in conjugation yield, in vivo stability, and immunogenicity (Powell et al. 1993; Fitzmaurice et al. 2000; W. Zeng et al. 2001). In addition to linear coupling strategies, peptides can also be assembled in branched geometries as in MAPs on lysine scaffolds (Tam 1988; Tam et al. 1990; Lu et al. 1991; Ahlborg 1995; Fitzmaurice et al. 1996; reviewed by Nardelli and Tam 1995). In MAPs, the orientation appears to be less critical for immunogenicity, and optimal MAP constructs were shown to contain equimolar amounts of BCEs and TCEs (Tam et al. 1990). Enhanced immunogenicity of branched peptides seems to be the result of a higher resistance of MAPs to enzymatic degradation and more efficient antigen presentation (Fitzmaurice et al. 2000).

IMMUNE RESPONSE TO PEPTIDE-CARRIER CONJUGATES

Conjugation of a (small) BCE to a (bulky) carrier protein tends to divert the immune response to the larger immunogenic carrier protein and away from the (peptide) epitope (Herzenberg and Tokuhisa 1980; Schutze et al. 1985; Etlinger et al. 1988). Pre-existing antibodies against the carrier protein may influence the immunogenicity of the conjugate, although this does not seem to be a major obstacle at least in the case of polysaccharide conjugate vaccines (Eskola et al. 1990; Kurikka et al. 1996). In the case of an experimental peptide-conjugate vaccine considerable differences between the resistance to pre-existing antibodies of TT and DT were observed (Putz et al. 2004). Peptide-specific epitopic suppression was stronger after passive priming with carrier or conjugate antibodies. DT as a carrier was less susceptible to suppression than TT and suppression could be overcome by boosting (Putz et al. 2004), as also shown for polysaccharide conjugates (Sarvas et al. 1992). The ability to provide T-cell help without diverting the immune response is perhaps the major advantage of using a defined T-helper epitope.

ONE OR MORE EPITOPES

Important mutations in the targeted epitopes of pathogens may require the combination of peptides corresponding to several nonoverlapping neutralizing epitopes or a mix of mutated peptides of the same epitope. Vaccines based on single epitopes may favor the development of escape mutants. In this case, the epitope vaccines should include variants of a given epitope (Wang et al. 2001) or more than one BCE. This can be produced by chemical polymerization (Patarroyo et al. 1988), as MAPs (Tam et al. 1990), multiple antigen constructs (Yang et al. 1997), or polyoximes (Nardin et al. 1998), or by genetic fusion (Shi et al. 1999; Theisen et al. 2000; Bouche et al. 2003).

Noninvasive routes of delivery

Some experimental vaccines have also been tested by nasal delivery using cholera toxin (CT) from *Vibrio cholerae* (Bergquist et al. 1998) and heat-labile enterotoxin from *Escherichia coli* (LT, Hathaway et al. 1995; Partidos et al. 1996), or nontoxic mutants as mucosal adjuvants (Di Tommaso et al. 1996; Yamamoto et al. 1998). CpG (reviewed by Krieg 2002) and immunostimulating complexes (ISCOM) (Sjolander et al. 2001) have been proposed as mucosal adjuvants and proteosomes as carrier proteins (Levi et al. 1995; Mallett et al. 1995) for intranasal immunization in humans (Haneberg et al. 1998; Oftung et al. 1999). Studies also seem to suggest that peptides can be delivered through the bare skin when mixed with LT, although the efficiency of this route remains to be demonstrated (Partidos et al. 2001; MM Putz and CP Muller, unpublished data).

Targeting selected epitopes

PROTEINS: A CHOICE OF EPITOPES

All currently licensed vaccines and most of those that are in clinical trials are meant to induce a strong neutralizing and protective immune response against pathogens prone to mutations in genetically diverse human or animal populations. The efficacy of these vaccines, irrespective of genetic variability of the host or pathogen, relies on the ability of the immune system to select from a large number of epitopes (TCEs or BCEs). In prophylactic vaccines, the exact epitopes involved in the response are normally of little clinical interest. With the advent of recombinant technology, we have learned to appreciate the advantages of guiding immune reactions against defined proteins of a pathogen and this is now being exploited in numerous experimental and a few licensed recombinant vaccines. In contrast to protein subunit vaccines, peptides rely on only a few epitopes of an antigen. Relative advantages such as chemical stability, biological safety, and low production costs normally do not outweigh the low (crossreactive) immunogenicity of peptide vaccines in different genetic contexts of hosts and pathogens.

PEPTIDES: AN EPITOPE OF CHOICE

Immunologically, the most important feature of peptide vaccines or other epitope vaccines is their ability to target defined epitopes. It has been proposed, for instance, to use peptides complementary to major antigenic regions of autoantigens to induce anti-idiotype antibodies for the treatment of autoimmune diseases (reviewed by Weathington and Blalock 2003). Peptide-induced anti-idiotype antibodies have also been successfully used to treat B-cell lymphomas (Hsu et al. 1996, Bendandi et al. 1999; Table 4). Peptides are also useful to avoid undesired immune responses, such as non-neutralizing antibodies which block neutralizing antibodies, enhancing or tumor-stimulating antibodies, autoimmune responses, or the induction of tolerization or suppressor cells (Aichele et al. 1995; Toes et al. 1996a, b). When the use of whole pathogens or proteins is limited by important constraints, epitope-based vaccines are unrivalled by other approaches. Although peptides may outrun other epitope immunization strategies, alternatives such as DNA minigenes (see

Naked DNA vaccines) or recombinant polyepitopes (reviewed by Suhrbier 2002) should also be considered. Essentially every feature of peptide vaccines has to be evaluated against competing vaccine technologies. There are still only few examples where a vaccine would clearly benefit from selected beneficial BCEs or from excluding detrimental BCEs, but applications are emerging for the treatment of autoimmunity (Weathington and Blalock 2003), allergies, and malignancies (Table 4), as well as infectious diseases (see below).

An example of a prophylactic epitope vaccine

The following describes one of the few examples of a prophylactic vaccine strategy against a pathogen where an epitope approach may be specifically justified. Infants are partially protected against measles by transplacentally acquired maternal antibodies. However, many children lose these antibodies within the first months of birth. As a result they become susceptible to measles before they can be immunized with the current live-attenuated vaccine recommended only at 9–15 months of age (Muller 2001a; Putz and Muller 2003). At this age, measles is associated with many complications and a high mortality rate. To close this susceptibility gap in infants, we developed an immunization strategy based on two subdominant sequential epitopes of the measles virus (MV) hemagglutinin protein (Ziegler et al. 1996; Fournier et al. 1997). Peptides corresponding to these sequential epitopes induce neutralizing and protective antibodies against the virus, but are not neutralized themselves by passively acquired antibodies induced by natural measles infection or after immunization with whole virus (El Kasmi et al. 1999a, 2000). Antibodies against measles surface glycoproteins provide full protection even in the absence of a T-cell response. In particular, newborns are solely protected by passively acquired maternal antibodies. Despite immaturity of their immune system, newborns and infants are capable of developing vigorous and protective antibody responses against proteins (e.g. DT and TT). In fact, during their early lives, antibodies are the main mechanisms of vaccine-induced protection of infants.

The generation of protective antibodies against the peptides requires a vigorous T-helper (Th) 2 response.

Table 4 *Experimental peptide vaccines against tumor antigens tested in cancer patients*

Tumor	Tumor antigen	Peptide vaccine formulation	Immunological outcome/clinical outcome	Reference
Adenocarcinoma (breast, ovary, colon)	HER-2	CTL epitope (9-mer) + IFA	Peptide-specific CTL in 3/4. No clinical response	Zaks and Rosenberg (1998)
Adenocarcinoma (breast, ovary, lung)	HER-2	3 peptides (15–18-mers) each with overlapping Th and CTL epitopes + GM-CSF	CTLs in 86% of patients. Peptide-specific CTLs kill HER-2 expressing tumor cells. T-helper response against peptide (14/18) and against HER-2 protein (up to 50%). Immune response lasted > 1 year. Tumor not evaluable	Knutson et al. (2001)
Adenocarcinoma (breast, ovary, lung)	HER-2	2 mixtures of 3 Th epitopes (15–18-mers, ICD, ECD) + GM-CSF	T-cell proliferation against peptides (8/8) and protein (6/8). Tumor not evaluable	Disis et al. (1999, 2000); Disis and Cheever (1998)
Adenocarcinoma (breast, ovary, lung)	HER-2/neu	3 mixtures of 3 T-helper epitopes + GM-CSF	T cells to peptides in 92%, 68% to protein	Disis et al. (2002)
Adenocarcinoma (breast, ovary)	HER-2/neu	9-mer CTL epitope + GM-CSF	CTLs in 2/4	Knutson et al. (2002)
Adenocarcinoma (breast, lung)	HER-2/neu	Mixtures of 4 peptide T-helper epitopes	T-cell response in 25% of patients	Salazar et al. (2003)
Adenocarcinoma (breast, ovary, pancreas)	MUC-1	Synthetic mucin polypeptide core (105-mer) with 5 repeated epitopes + BCG	Infiltration of T cells at immunization site in 37/55. Increased CTLs in 7/22. DTH in 3/63. No clinical response.	Goydos et al. (1996)
Adenocarcinoma expressing CEA	CEA	CTL epitope (9-mer) + Detox PC	CTLs secreting low levels of IFN-α in 1/5	Arlen et al. (2000)
Colon, breast, ovary, pancreas	CEA	CAP-1 (9-mer + DC)	No DTH. 1/19 minor clinical response.	Morse et al. (1999)
Thyroid carcinoma	CEA	CAP-1 (9-mer + DC)	1/7 PR	Schott et al. (2001)
Pancreas carcinoma	K-ras	Mononuclear cells pulsed with peptide (17-mer)	$CD4^+$ in 2/5. No clinical response	Gjertsen et al. (1995, 1996a, b)
	K-ras	ras (13-mer) + Detox	$CD4^+$ in 3/10, $CD8^+$ in 3/10 against peptide. No clinical response	Khleif et al. (1999)
	K-Ras	4 peptides (17-mers) with mutated TCE + GM-CSF	Peptide-specific T cells or DTH of 25/43. Significant increase in survival	Gjertsen et al. (2001)
Prostate carcinoma	Prostate acid phosphatase	CTL peptide + GM-CSF	> 50% reduction of PSA in 3/31.	Small et al. (2000)
	PSMA	CTL peptides + DC (PSM-P1, PSM-P2)	DTH, $CD8^+$ response. 19/62 reduction in PSA. 2/25 CRs, 6 PRs	Murphy et al. (1999a); Tjoa et al. (1999); Lodge et al. (2000); Salgaller et al. (1998)
	PSMA	PSM-P1 (LLHETDSAV) $\pm$ DC	Specific CTLs in few patients	Murphy et al. (1996)
		PSM-P2 (ALFDIESKV) $\pm$ DC	7/51 reduction in PSA	Tjoa et al. (1997)
	PSMA	PSM-P1 peptide, PSM-P2 peptide	DTH, $CD8^+$. No clinical response	Murphy et al. (2000)

Tumor	Tumor antigen	Peptide vaccine formulation	Immunological outcome/clinical outcome	Reference
Bladder cancer	MAGE-3	CTL peptide + DC	1/4 PR	Nishiyama et al. (2001)
HPV-associated carcinomas	E7 of HPV16	86-mer CTL peptide + PADRE + Montanide ISA51	Induction of CTLs. No clinical response	Steller et al. (1998)
	E7 of HPV16	10-mer + 8-mer + PADRE	Response to PADRE (4/12). No CTL response. No clinical response	Van Driel et al. (1999); Ressing et al. (2000)
E7 protein of HPV16		CTL epitope (9-mer) plus a CTL-pan Th (PADRE) lipopeptide conjugate + IFA	Epitope-specific CTL activity in 10/16. No DTH. 3/17 CRs, 9/17 PRs	Muderspach et al. (2000)
Chronic myelogenous leukemia	Bcr-abl fusion protein, p210	5 peptides (9–25-mers) with Th and CTL epitopes + QS21	Peptide-specific T-cell proliferation in 50% of patients. No CTL activity	Pinilla-Ibarz et al. (2000)
Acute myeloid leukemia	WT1	9-mer CTL peptide + KLH + GM-CSF	CR in 1/1	Mailander et al. (2004)
Melanoma (metastatic)	gp100	Modified CTL epitope (9-mer), + IFA + either IL-2, GM-CSF, or IL-12	Tumor regressions in 6/16 patients tested. IFA + IL-2. IFA + GM-CSF: 0/13. IFA + IL-12: 0/14	Rosenberg et al. (1999)
Melanoma	MAGE-3	CTL peptide (9-mer), no adjuvant	No peptide-specific CTLs. 3/25 CRs, 4/25 PRs. 2/25 disease free for 2 years	Marchand et al. (1999)
Melanoma	MAGE-3	CTL peptide (9-mer) with pan class II peptide + IFA	Tumor response not evaluable (n = 18)	Weber et al. (1999)
Melanoma	MAGE-3	CTL peptides + DC	8/11 peptide-specific CTLs. 54% tumor response (single metastases)	Thurner et al. (1999)
Melanoma	MAGE-3	CTL peptide	Peptide-specific CTLs in 4/9 responding; in 1/14 non-responding patients. 39% tumor response	Coulie et al. (2002)
Melanoma	MAGE-3	DC pulsed with Th epitope	Majority of patients developed peptide-specific Th cells.	Schuler-Thurner et al. (2002)
Melanoma and others	NY-ESO-1	3 CTL peptides (9–11-mers) ± GM-CSF	4/12 peptide-specific CTLs, 4/12 DTH. 7/12 SD	Jager et al. (2000a)
Melanoma	Tyrosinase	4 CTL peptides (9-mers) + GM-CSF	4/18 peptide-specific CTLs. 1/5 mxR, 2/5 SD	Scheibenbogen et al. (2000)
Melanoma	Tyrosinase	CTL peptides (9-mer) + QS21	0/7 tumor response	Lewis et al. (2000)
Melanoma	gp100	3 CTL peptides (9-mer) + IFA	1/20 tumor response	Salgaller et al. (1996)
Melanoma	$gp100_{209–217}$ 210M	Modified CTL epitope (9-mer) + IFA or +IFA + IL-2	Peptide-specific CTLs in 91%. IFA: 0/11 tumor responses. IFA + IL-2; 1/31 CRs. 12/31 PRs	Rosenberg et al. (1998)
Melanoma	gp100	CTL epitope (9-mer) + 1. QS21 or Montanide ISA-5I2. Tetanus helper peptide + QS21 or Montanide ISA-5I3. Gp100-tetanus 24-mer + QS21 or Montanide ISA-5I	Peptide-specific Th and CTL response in 79% and 14% of patients respectively. Tumor not evaluable (n = 20). 75% survival after 4.7 years	Slingluff et al. (2001)
Melanoma	gp100 (210M), tyrosinase	Modified CTL epitope (9-mer) + IFA ± IL-12	37/42 peptide-specific CTLs. Tumor not evaluable. Increased disease-free survival	Lee et al. (2001)
Melanoma	gp100, tyrosinase	4 CTL epitopes (9-mers) + GM-CSF + Montanide ISA-51	CTL responses to peptides in 2–5/5 tumor-specific CTLs (5/5) in vitro	Yamshchikov et al. (2001)
Melanoma	gp100, tyrosinase	CTL peptides ± GM-CSF	37/42 peptide-specific CTLs; improved immunization. Tumor not evaluable	Weber et al. (2003)

Table 4 *Experimental peptide vaccines against tumor antigens tested in cancer patients (Continued)*

Tumor	Tumor antigen	Peptide vaccine formulation	Immunological outcome/clinical outcome	Reference
Melanoma	Melan-A/MART-$1_{27–35}$	CTL epitope (9-mer) + IFA	7/8 peptide-specific CTLs. 1/18 PRs	Cormier et al. (1997)
Melanoma (resected)	Melan-A/MART-$1_{27–35}$	CTL epitope (9-mer) + IFA + CRL 1005	IFN-γ-secreting peptide-specific T cells in 12/20. Tumors not evaluable because of resection. Increased disease-free survival correlated with immune response	Wang et al. (1999a)
Melanoma	MART-1	CTL peptide (10-mer) + SB-AS 2 adjuvant/Montanide	Peptide-specific CTLs	Pittet et al. (2001)
Melanoma	MART-1, gp100	CTL peptides + DCs + no adjuvant	1/5 developed peptide-specific CTLs. Tumor response 1/7	Panelli et al. (2000)
Melanoma	Melan-A/MART-1, tyrosinase, gp100/Pmel17	6 CTL epitope (9, 10 mers)	5/6 DTH, 2/6 SD	Jaeger et al. (1996)
Melanoma	MART-1, tyrosinase, gp_{100}	CTL peptides + DC	2/28 CRs, 1/28 PRs	Lotze et al. (2000)
Melanoma	Melan-A/MART-1, tyrosinase, gp100, MAGE-3	CTL peptides + DC	16/18 peptide-specific CTLs. Immunity to peptides correlated with delayed tumor progression. Regression of some metastasis	Banchereau et al. (2001)
Melanoma	Tumor lysate	Peptide cocktail or tumor lysate + DC	DTH reaction to peptide-pulsed DC in 11/16. 31% tumor response	Nestle et al. (1998)
Melanoma	$gp100_{209–217}$210M0	Modified CTL peptide alone or modified CTL peptide + IL-2	Peptide-specific CTLs in 7/7. 0/7 tumor response	Lee et al. (1999)
			Peptide-specific CTLs in 1/11. 5/11 tumor response	
		Modified CTL peptide + IL-12	Peptide-specific CTLs in 4/5. 0% tumor response	
Melanoma	N-ras	ras (25-mer) + GM-CSF	DTH in 8/10, $CD4^+$ in 2/10. Clinical response, not examined	Hunger et al. (2001)
Melanoma	gp100, tyrosinase	4 CTL epitopes + GM-CSF + universal T-helper epitope + Montanide ISA-51	T-cell response in 42% patients.	Slingluff et al. (2003)
Melanoma	gp100 (210 M), MART-1	2 CTL epitopes	T-cell response in 95%. Clinical response in 0/22	Phan et al. (2003)
	gp100 (210 M), MART-1	2 CTL epitopes + 1 helper epitope	T-cell response in 50%. Clinical response in 1/19	
Melanoma	gp100, MART-1, tyrosinase	3 CTL epitopes + IFA + SD-9427	7/10 in ELISPOT essay. 11/12 in MHC-pep-tetramer essay	Pullarkat et al. (2003)
Melanoma	Melan-A	10-mer CTL peptide + rhIL-12	1/24 CRs, 1/24 PRs, 6/24 SD	Cebon et al. (2003)
Melanoma	Melanoma tyrosinase	9-mer CTL peptide + KLH + GM-CSF	T-cell response in 5/9	Scheibenbogen et al. (2003)
Melanoma	Tyrosinase	9-mer CTL peptide + KLH + GM-CSF	T-cell response in 2/2. 2 years disease-free recurred	Scheibenbogen et al. (2002)
Melanoma	MAGE-3	9-mer CTL peptide + KLH + GM-CSF	T-cell response in 2/9. Regression in 5/9	Coulie et al. (2002)

BCG, Bacillus Calmette–Guérin; CEA, carcinoembryonic antigen; IFA, incomplete Freund's adjuvant; MUC, mucin; PSA, peptide-specific antigen; PSMA, peptide-specific membrane antigen; rhIL-12, recombinant interleukin 12; SD, stable disease. See Table 1 for other abbreviations.

The induction of MV antibodies is complicated by observations of enhanced atypical disease after immunization with inactivated MV vaccine during the 1960s. This complication is now attributed to priming of nonprotective MV-specific Th2-biased cells (Polack et al. 1999). Thus, it is critical that the Th cells are unrelated to MV. Therefore, the peptides corresponding to the above sequential epitopes were conjugated to (unrelated) carrier proteins such as DT or TT. These peptide conjugates induced high levels of anti-peptide antibodies, which protected against MV utilizing TCEs of the carrier protein (Putz et al. 2004). Thus the risk of priming for measles-specific T cells was avoided and the main cause of atypical measles, i.e. an aberrant measles-specific Th2 priming, was precluded.

In this example the advantage of using a peptide as a protective BCE was a three-fold:

1. The peptide, in contrast to whole virus or viral proteins, was not susceptible to neutralization by pre-existing anti-whole virus antibodies.
2. By limiting the MV sequence to 20 amino acids priming by pathogenic TCEs was essentially avoided.
3. The relatively low immunogenicity and the short duration of an anti-peptide response may prove to be an asset here because protection of limited duration, at least against severe disease (to reduce complication rates and mortality, but not necessarily infection) is required, until the live-attenuated vaccine can be administered.

We have shown that this experimental vaccine is compatible both with pre-existing antibodies against the carrier protein DT and against whole MV, and that subsequent boosting with whole virus is possible (Putz et al. 2004).

CANDIDATE PEPTIDE VACCINES AGAINST BCES

Paramyxoviruses

MEASLES VIRUS

This single-strand, negative-sense RNA virus is the prototype morbillivirus (family of Paramyxoviridae). The current live-attenuated vaccine is poorly immunogenic in early infancy, as a result of the presence of neutralizing maternal antibodies passively acquired through the placenta and the immaturity of the infant immune system. Therefore a number of experimental vaccines based, for example, on recombinant MV proteins, viral and bacterial vectors, or naked DNA, have been developed (reviewed by Putz et al. 2003a). Among these numerous immunization strategies some are based on peptides of the hemagglutinin (H) and fusion (F) protein. MV-neutralizing antibodies are directed against both the F and the H glycoproteins, and sequential epitopes have been identified for both proteins. The rationale of peptides as a vaccine to protect during early infancy against measles is discussed in the previous section.

Steward and colleagues described two adjacent sequential epitopes contained within a short immunodominant region (F388–420) of the F protein (Partidos et al. 1991), crossreacting with sera from African children with acute measles (Atabani et al. 1997). Co-linearly synthesized with one or two copies of a promiscuous TCE (Partidos and Steward 1990), one of these peptides was immunogenic in mice and induced MV-crossreactive and -neutralizing antibodies (Atabani et al. 1997). Passive transfer of anti-peptide serum partially protected mice against a challenge with a neuroadapted MV strain (Obeid et al. 1995; Atabani et al. 1997) and cross-protected against canine distemper virus, a related morbillivirus (Obeid et al. 1995). In addition, intranasal co-immunization with a synthetic peptide containing two copies of a TCE and one copy of a BCE together with cholera toxin B (CTB) induced MV-neutralizing antibodies and conferred protection in the mouse model (Hathaway et al. 1995, 1998). When copies of the BCE (Obeid et al. 1995) and an N protein TCE were fused C terminally to the secretion signal of *E. coli* hemolysin and expressed by the attenuated *S. typhimurium* aroA strain, an MV-specific humoral and cellular immune response was induced after oral immunization which partially protected susceptible mice (Verjans et al. 1995; Spreng et al. 2000).

Two sequential BCEs have been identified on the H protein by screening a panel of neutralizing and protective mAbs against a complete set of overlapping synthetic peptides (Ziegler et al. 1996; Fournier et al. 1997). Several mAbs reacted with peptides defining the neutralizing epitope (NE) (H236–256) and blocked hemolysis of monkey erythrocytes without inhibiting hemagglutination, suggesting that they acted at the functional interface of the H and F protein and did not inhibit virus binding to host cells (Fournier et al. 1997). Co-linear synthesis of this BCE in different orientations and copy numbers with various TCE-generated peptides was capable of inducing antibodies that neutralized MV in vitro (El Kasmi et al. 1998). After passive transfer, these sera were shown to protect young mice against a lethal challenge with the neuroadapted MV strain (El Kasmi et al. 1999a). Interestingly, NE peptides were not recognized by mouse sera generated by immunization with whole virus, and protective levels of passively transferred anti-MV antibodies did not suppress a humoral response against the NE peptide (El Kasmi et al. 1999a). Mimotopes generated against mAbs of this epitope were highly antigenic but induced no neutralizing antibodies (Deroo et al. 1998; El Kasmi et al. 1998, 2000).

Another set of mAbs identified a second sequential epitope of the H protein, the hemagglutinin noose epitope (HNE) (H381–400). This sequence contains

three cysteine residues (in positions 381, 386, and 394) which are conserved in all morbilliviruses (Ziegler et al. 1996), and HNE peptides formulated in Complete Freund's adjuvant (CFA) induced MV-crossreactive and -neutralizing sera even in the presence of protective levels of whole virus-specific antibodies (El Kasmi et al. 2000). The HNE domain is a highly conserved, subdominant, antigenic determinant (Putz et al. 2003b) and it was shown that sera of measles in late-convalescent women of child-bearing age do not recognize this peptide (Ziegler et al. 1996). These results suggest that passively acquired maternal antibodies in infants would not interfere with the immune response to this peptide. The protective binding motif of this peptide was revealed using surface plasmon resonance and a shortened, optimized sequence of the HNE, conjugated to immunogenic carrier proteins (DT or TT) and an adjuvant licensed for human use (alum) induced MV-crossreactive and protective antibodies (Putz et al. 2003b, 2004). Co-administration of the HNE conjugates with cholera toxin induced MV-crossreactive and -protective antibodies after intranasal and lower levels of peptide-specific antibodies following transcutaneous immunization (MM Putz and CP Muller, unpublished results).

Transgenic edible plants have been used to express viral antigens and chimeric high-molecular-weight polyepitopes. Such constructs (24.5–45.5 kDa), based on the permutational recombination of multiple paired copies of the HNE and NE sequences with a promiscuous, TT-derived TCE were developed and expressed in transgenic carrots (Bouche et al. 2003). One of these polyepitope proteins was shown to induce high levels of neutralizing antibodies in mice. These sera neutralized a wide range of wild-type MV isolates of different genotypes and from geographic origins (Bouche et al. 2003). Moreover, these sera neutralized all wild-type isolates tested irrespective of mutations in the HNE epitope (unpublished results).

RESPIRATORY SYNCYTIAL VIRUS

This single-strand, negative-sense RNA virus (pneumovirus of the Paramyxoviridae family) causes a severe lower respiratory tract infection in infants and immunosuppressed individuals. Despite decades of research, no vaccine has been licensed to protect against this disease. The numerous experimental vaccines also include a strategy based on synthetic peptides.

Residues 124–203 of the G glycoprotein represent a major immunogenic domain. When mice were immunized with a recombinant vaccinia virus expressing the corresponding peptide, protein G-crossreactive antibodies were induced and viral load in the lungs was significantly reduced following intranasal challenge with live respiratory syncytial virus (RSV) (Simard et al. 1995). Interestingly a short polymer of 14 peptides (amino acids 174–187), derived from this domain and coupled to keyhole limpet hemocyanin (KLH) conjugate, was sufficient to reduce viral load in the lungs of challenged animals (Simard et al. 1997). The same peptide epitope, inserted into the pIII coat protein of a recombinant bacteriophage, also elicited high levels of RSV-specific antibodies which conferred complete resistance to an RSV challenge (Bastien et al. 1997). Intranasal delivery of this peptide epitope mixed with CT also gave complete protection (Bastien et al. 1999).

By screening a random combinatorial octameric peptide library, a number of peptide mimotopes were identified against a neutralizing and protective mAb specific for the RSV F protein (Chargelegue et al. 1997). When mice were immunized with MAP constructs carrying these peptide mimotopes mixed with a promiscuous Th epitope peptide and CFA, virus-crossreactive antibodies were elicited which neutralized RSV in vitro. In vivo a significant decrease of infectious particles was found in the lungs of immunized mice (Chargelegue et al. 1997, 1998). A significant reduction of viral load was also achieved in mice immunized intranasally with cytotoxic T lymphocytes (CTL) epitope peptides (Hsu et al. 1998). When mice were immunized subcutaneously with a cocktail containing the MAP-mimotope construct, and Th and CTL peptides emulsified in incomplete Freund's adjuvant (IFA), an almost 200-fold reduction in the viral load was detected after challenge in comparison to the mice immunized with either of the peptides alone (Hsu et al. 1999). The RSV infection was more effectively cleared by a combined humoral and cellular response induced by the peptide cocktail than either peptide-induced humoral or cellular immunity alone. With the difficulties involved in developing an RSV vaccine by any strategy, the peptide approach is worth pursuing, although it is not clear why an approach based on defined epitopes would be an advantage.

Orthomyxovirus

INFLUENZA A VIRUS

The development of efficient influenza vaccines is complicated by the many subtypes and high mutation rates and of the virus and its reassortment. Thus, this virus is less than ideal for the development of an epitope-based vaccine. None the less, various hemagglutinin-derived peptides, conjugated to TT and immunized with CFA, induced antibodies inhibiting hemagglutination and virus growth in vitro and partially protecting mice against challenge with different influenza strains (Muller et al. 1982; Shapira et al. 1984). Peptides may thus induce a broader crossreactive and protective humoral response than expected. A similar observation was made with a polyepitope consisting of repeats of the MV HNE epitope, which induced antibodies neutralizing several MV strains with mutated critical contact residues in their HNE domain (Bouche et al. 2004).

Protective antibodies against influenza were also elicited using liposome-conjugated peptides even without CFA (Friede et al. 1994), and protective immunogenicity was further improved with cyclic peptides, assuring a better structural mimicry of the viral antigenic determinant (Muller et al. 1990).

Picornaviruses

FOOT-AND-MOUTH DISEASE VIRUS

This member of the aphthoviruses is one of the most infectious veterinary viruses, causing a devastating disease of livestock. Immunization with an inactivated whole virus precludes the possibility of distinguishing between immunized and infected animals. A safe, nonreplicating, subunit vaccine inducing a protective response in cattle and swine, against both disease and infection, and which could be differentiated from natural infection, would be an asset. Among the four structural proteins VP1–VP4, VP1 induces neutralizing antibodies (Pfaff et al. 1982), targeting two dominant antigenic sites (A and C). Synthetic peptides, corresponding to these domains, conjugated to KLH-induced antibodies that crossreacted with foot-and-mouth disease virus (FMDV) particles (Parry et al. 1988), neutralized virus infectivity in vitro, and protected in vivo (Bittle et al. 1982). Protective immunity was achieved in animal models, as well as in the natural host species, i.e. swine and cattle (DiMarchi et al. 1986; Morgan and Moore 1990). Chimeric peptides including epitopes of two different serotypes protected guinea-pigs against both serotypes (Doel et al. 1992). Serotype variability and possibly escape by mutation of this RNA virus may be overcome by the combination of peptides. In larger immunization trials of cattle with peptides derived from site A and C, coupled to a VP1-derived immunodominant TCE (Collen et al. 1991), only 40 percent protection was achieved (Taboga et al. 1997). Protection was undermined by the rapid generation of escape mutants in immunized animals (Taboga et al. 1997). In a more recent study with a vaccine consisting of unconjugated peptides with the built-in adjuvant tripalmitoyl-*S*-glyceryl-cysteinylserylserine (P3C) (Wiesmüller et al. 1989; Hohlich et al. 2003), protection did not correlate with the detection of high levels of antibody. Instead, strong peptide-specific T-cell responses were detected, (Hohlich et al. 2003). Retro-all-d-peptide analogs of site A (Muller et al. 1995; Benkirane et al. 1996b) further improved the immunogenicity and induced high levels of neutralizing and protective antibodies (Briand et al. 1997).

Various different peptide formulations were used. Neutralizing and protective antibodies were obtained by peptides either conjugated to an immunogenic carrier protein (e.g. KLH, TT; Bittle et al. 1982), unconjugated P3C peptides (Wiesmüller et al. 1989; Hohlich et al. 2003) or delivered in liposomes (Francis et al. 1985), as MAP constructs (Francis et al. 1991) or emulsified in oil adjuvants (Taboga et al. 1997; Wang et al. 2001, 2002a). Site A epitope is a highly disordered loop within the VP1 (Acharya et al. 1989). Crossreactive immunogenicity of a synthetic peptide epitope results from the right balance between rigidity and flexibility, and cyclization of site A peptide was shown to produce a more stable immunogenic structure (Camarero et al. 1993; Valero et al. 2000). The peptide was also constrained in recombinant proteins (Benito and Villaverde 1994; Benito and Van Regenmortel 1998) and, if one gave a better mimic of the viral epitope than conjugated synthetic peptides, others did not (Benito and Van Regenmortel 1998).

POLIOVIRUS

At the present, late stage of polio eradication, the development of an effective nonreplicating vaccine becomes an important issue. Although the inactivated Salk vaccine would be suitable, current production capacities are not sufficient. The development of a peptide vaccine is complicated by the three serotypes, each requiring its own neutralizing antibodies. Several VP1- and VP2-derived peptide epitopes were identified and shown to induce virus-neutralizing antibodies in various animal models, including guinea-pigs and rabbits when conjugated to carrier proteins (Emini et al. 1983, 1984a; Jameson et al. 1985). However, crossreactive immunogenicity was modest, as less than 30 percent of the animals developed neutralizing antibodies.

HEPATITIS A VIRUS

A sequential neutralizing epitope has been identified on the VP1 protein by comparison of surface probability profiles between hepatitis A virus (HAV) and poliovirus (Emini et al. 1985), despite minimal homology between their primary and secondary structures. Virus cross-reacting and in vitro neutralizing antibodies were induced with a VP1-peptide BSA (Emini et al. 1985), KLH conjugate, or MAP constructs (Haro et al. 1995). Two other sequential BCEs were reported on the VP2 (Robertson et al. 1989) and VP3 surface proteins (Wheeler et al. 1986). Each of the three VP1, VP2, and VP3 peptides, encapsulated in multilamellar liposomes, induced virus-neutralizing antibodies (Bosch et al. 1998). The best virus-crossreactive/neutralizing antibodies were obtained with VP3-derived peptide (Bosch et al. 1998). However, this strategy would offer no obvious advantage over current vaccines.

Flavivirus

HEPATITIS C VIRUS

This is a major cause of acute and chronic hepatitis with 180 million cases worldwide. The development of an effective vaccine against hepatitis C virus (HCV) has been so far unsuccessful. The hypervariable region 1 (HVR1) of the main E2 envelope protein has been identified as a target of neutralizing antibodies (Farci et al.

1996). A consensus sequence of HVR1 was genetically fused to the C terminus of the B subunit of CTB and expressed in plants using a tobamoviral vector (Nemchinov et al. 2000). Intranasal immunization of mice with a crude plant extract containing the recombinant chimeric HVR1-CTB protein induced antibodies crossreacting with HCV-like particles (Nemchinov et al. 2000). HCV-crossreacting antibodies were also elicited in mice using HVR1-derived peptides conjugated to KLH (Li et al. 2001) or recombinantly expressed polyepitope constructs (Li et al. 2003), and in rabbits with MAPs containing mimotope peptides (Roccasecca et al. 2001).

Retrovirus

HUMAN IMMUNODEFICIENCY VIRUS (HIV)

Despite worldwide efforts, there is no vaccine available against human immunodeficiency viruses 1 and 2 (HIV-1 and HIV-2). The characteristic viral envelope spike is formed by monomers of the two surface glycoproteins gp41 and gp120 and carries several well-characterized BCEs targeted by broadly reactive human neutralizing mAbs (Burton et al. 2004). For safety reasons, vaccine development has principally focused on subunits rather than live attenuated or chemically inactivated virus. The development of an effective vaccine is particularly difficult because there is no natural recovery from infection, which could serve as a model for a protective immune response, but neutralizing antibodies are (again) thought to be important for protection. The situation is further complicated of course by antigenic variability.

Most of the BCE experimental vaccines against HIV are based on the 'principal neutralizing domain', i.e. the third variable domain (V3) of the gp120 glycoprotein of HIV-1. MAPs, derived from this sequence, coupled to the 'built-in' adjuvant tripalmitoyl-*S*-glycerylcysteine (Deres et al. 1989) and formulated in liposomes, induced in laboratory animals gp120-specific antibodies which neutralized virus infectivity in vitro (Defoort et al. 1992b; Nardelli et al. 1992). However, neutralizing antibodies were type specific and crossreactivity in enzyme-linked immunosorbent assay (ELISA) with other strains was weak (Nardelli et al. 1992). 'Cluster peptides', consisting of synthetic peptide constructs of the V3 loop and overlapping multideterminant Th epitopes of gp160, induced V3-specific neutralizing antibodies in several strains of mice (Berzofsky et al. 1991; Ahlers et al. 1993). Intranasal immunization with free V3 loop peptides and the mucosal adjuvant CT generated HIV-1-neutralizing antibody responses in two strains of mice (Staats et al. 1996). In addition to high serum anti-peptide responses, significant vaginal anti-peptide IgG and IgA levels were obtained (Staats et al. 1996). Neutralizing secretory IgA antibodies were also induced after oral delivery of multivalent MAPs mixed with CT (Bukawa et al. 1995; Kato et al. 2000). Systemic and mucosal antibody responses were further improved by co-administration of proinflammatory cytokines, such as the interleukins IL-1α, IL-12, and IL-18, instead of CT (Bradney et al. 2002).

Synthetic peptide vaccines have also been tested in clinical trials with encouraging long-term safety profiles when adjuvants other than IFA were used. Long-lasting, peptide-specific, neutralizing humoral responses were obtained with a purified protein derivative (PPD) conjugate vaccine without the use of an adjuvant (Rubinstein et al. 1995, 1999). HIV-seropositive vaccinees over time exhibited a uniform increase in antibodies capable of neutralizing laboratory-adapted and primary isolates of HIV-1. Highest titers were observed after 12 months in a regimen where the peptide conjugate was inoculated intradermally, monthly for the first 3 months and then at 3-month intervals to 18 months. In three of seven patients, a progressive decline in viral loads occurred (Rubinstein et al. 1999). Although viral mutants with amino acid substitutions within the V3 loop sequence appeared in these three patients during the immunization program, virus loads remained at low levels for several months (Lenz et al. 2001). However, about a year after discontinuation of immunization, in six patients viremia was at preimmunization levels or higher and was paralleled by a loss in V3 loop-specific antibodies (Rubinstein et al. 1999). An unconjugated, octameric, branching, V3 loop peptide adsorbed on alum induced in vitro neutralizing antibodies in eight of ten HIV-1-uninfected, healthy adults after intramuscular administration (Gorse et al. 1996). Whereas the same vaccine formulation displayed a similar high neutralizing efficacy (19 of 20 vaccinees) in a trial in Bangkok, Thailand (Phanuphak et al. 1997), lower seroconversion rates (3 of 13 vaccinees) were observed in a trial in Longchuan County, China (Li et al. 2001). This octameric peptide vaccine was weakly immunogenic (4 of 24 vaccinees seroconverted) when delivered subcutaneously in combination with alum (Kelleher et al. 1997), and after oral administration of peptides encapsulated in biodegradable microspheres no significant humoral, cellular, or mucosal immune responses were found (Lambert et al. 2001a).

However, sterilizing immunity to HIV-1 will most probably be achieved only through a combination of protective antibody and CTL responses. Promising results have been obtained with peptide vaccines eliciting cellular immune responses (Letvin 1998; Suhrbier 2002).

Parvoviruses

CANINE PARVOVIRUS

The use of a peptide vaccine against canine parvovirus (CPV) was among the first to demonstrate the induction

of protection in the natural host (Langeveld et al. 1994b). Among the three structural proteins VP1–VP3 of the virus capsid, VP2 is the major immunogen. Immunization with two overlapping peptides of the N-terminal domain of VP2 conjugated to KLH protected dogs against a lethal challenge with CPV, despite the intriguing observation that virus-neutralizing antibodies were not detected in any of the immunized and protected animals before challenge (Langeveld et al. 1994a, b). Protection was attributed to the high flexibility of the epitope and its functional importance for viral replication (Langeveld et al. 1994a). Efficacy of the peptide vaccine was shown to result from two distinct but overlapping epitopes, each of which induced neutralizing antibodies in rabbits (Langeveld et al. 1994b; Casal et al. 1995). Mutation rates are low in this DNA virus (in comparison to RNA viruses) and this N-terminal epitope is conserved in different virus isolates (Parrish et al. 1988), including the three closely related virus species, mink enteritis virus (MEV), feline panleukopenia virus (FPLV), and raccoon parvovirus. Thus, the same epitope could be used in three important animal species: dogs (Langeveld et al. 1994a), cats (Langeveld et al. 2001a), and band minks (Langeveld et al. 1995). Immunization with the CPV-derived peptide conjugated to KLH protected minks against MEV (Langeveld et al. 1995). When the corresponding MEV oligonucleotide coding sequence was inserted into the plant virus, cowpea mosaic virus, the epitope was expressed on the surface of the chimeric virus particles propagated in the black-eyed bean, an edible plant. Subcutaneous injections of minks with recombinant virus-like particles protected against clinical disease and virtually abolished shedding of virus after challenge with virulent MEV (Dalsgaard et al. 1997). Chimeric virus-like particles also protected dogs from a lethal challenge with CPV (Langeveld et al. 2001b). A multivalent vaccine based on peptides of CPV, canine distemper virus (CDV), and *Pseudomonas aeruginosa* could be a commercially viable strategy because they would protect dogs against two important canine diseases and minks against the three major diseases in mink farming.

Hepadnavirus

HEPATITIS B VIRUS

It is estimated that 400 million people are chronically infected worldwide with hepatitis B virus (HBV). Protective antibodies in humans mostly target the hepatitis B virus surface antigen (HBsAG). Several continuous BCEs have been identified on HBsAg (Gerin et al. 1983). When coupled to a carrier protein, such as KLH, some of these peptides induced a weak, but partially protective, humoral response in chimpanzees (Gerin et al. 1983; Itoh et al. 1986). Protective immune responses were also obtained with unconjugated, longer polymers of 55 peptides (Emini et al. 1989). MAPs induced increased antibody responses in rabbits (Tam and Lu 1989). A peptide-based approach using CTL epitopes has also been explored (reviewed by Engler et al. 2001). After initial encouraging results (Vitiello et al. 1995; Livingston et al. 1997, 1999) CTL responses were weak in later human trials (Heathcote et al. 1999).

Papovavirus

HUMAN PAPILLOMAVIRUS

Human papillomavirus (HPV) is a double-stranded, circular DNA virus with more than 100 genotypes. In particular the high-risk genotypes (HPV16, -18, -31, -33, and -45) are found in almost all cervical carcinomas. Experimental preventive and therapeutic vaccines against HPV-mediated cervical cancer were recently reviewed (Fausch et al. 2003; Roden and Wu 2003). A peptide from the E7 protein of HPV16 containing a BCE, a promiscuous T helper, and a CTL epitope were coupled to immunostimulatory carriers (ISCAR) (Tindle et al. 1995) or combined as polymeric conjugates (Fernando et al. 1995) with either CFA or ISCOMs. These constructs induced E7-crossreactive antibodies and E7-specific CTLs with in vitro killing activity (Tindle et al. 1995), and conferred in vivo protection against an E7 gene-transfected tumor cell inoculum (Tindle et al. 1995). Sequential neutralizing BCEs have also been identified of the L1 (major) and L2 (minor) structural proteins using mAbs (Kawana et al. 1998). A BSA-conjugated L2-derived peptide induced antibodies that crossneutralized HPV16 and -6 (Kawana et al. 1999). Intranasal immunization with the same epitope in TCE-containing chimeric peptides, mixed to CT, induced antibodies cross-binding to HPV6, -16 ,and -18, and neutralizing HPV11 authentic virions and HPV16 pseudovirions in vitro (Kawana et al. 1999, 2001). These results suggest that this BCE is shared by other genital HPVs and may induce broadly reactive, cross-neutralizing antibodies. Early safety and immunogenicity trials in humans were promising. Intranasal delivery of a linear polymer of 13 peptides without adjuvant induced antibodies neutralizing HPV15 and -52 (Kawana et al. 2003). Peptide vaccines targeting tumor-specific CTL responses are discussed later in the chapter.

Bacteria

NEISSERIA MENINGITIDIS SEROGROUP C

Most of the infections by *Neisseria meningitidis*, gram-negative encapsulated bacteria, are caused by any of the four prevalent serogroups: A, B, C, and Y. Polysaccharide-conjugate vaccines induce neutralizing antibodies against surface loops of class 1 outer membrane proteins (OMP),

which play a major role in protection. TT-based conjugates loaded with cyclic peptides derived from OMP induced mouse antibodies with bactericidal activity in vitro (Hoogerhout et al. 1995). Protective immune responses against experimental challenge were seen in mice with unconjugated, free peptides of the PorA and the OpaB outer membrane proteins (Koroev et al. 2000, 2001). Polysaccharides can be mimicked using peptides or anti-idiotype antibodies as surrogate antigens (reviewed by Monzavi-Karbassi et al. 2002). Immunization with mimotopes conjugated to DT induced antibodies crossreacting with the meningococcal outer-membrane lipo-oligosaccharide (Charalambous and Feavers 2000). Short peptides derived from the CDR sequences of protective anti-idiotype antibodies, and conjugated to proteosomes, induced antibodies protecting mice against a lethal dose of *N. meningitidis* (Westerink et al. 1995; Prinz et al. 2004). Mimotope peptides were also incorporated into DNA constructs. After DNA immunization, significant anti-polysaccharide antibody responses were induced, neutralizing bacterial activity in vitro and protecting against a challenge in vivo (Westerink et al. 2001; Prinz et al. 2003).

Several other peptide-based vaccines have been developed to protect against *Pseudomonas aeruginosa* (reviewed by Cachia and Hodges 2003) and group A streptococcus (reviewed by Olive et al. 2004) and others (see Table 1).

Parasites

MALARIA

This is by far the most important parasitic disease in humans, caused by four *Plasmodium* species (*P. falciparum*, *P. malariae*, *P. ovale*, *P. vivax*) and spread by female anopheles mosquitoes. More than 200 species are known to parasitize mammals (e.g. *P. berghei* and *P. yoelii* in mice, *P. knowlesi* in monkeys), birds, and reptiles. The development of a malaria vaccine is a difficult task for various reasons: the life cycle of malaria parasites in humans is complex with morphologically and antigenically distinct stages. There is a high degree of antigenic variation among *Plasmodium* species. Immunity is stage specific. An important part of the population does not respond to particular parasite antigens. Nevertheless, several peptide epitopes inducing neutralizing and protective antibodies have been identified on antigens of the pre-erythrocytic (e.g. circumsporozoite protein (CSP); thrombospondin-related anonymous protein (TRAP); liver stage antigen 3 (LSA-3)) and the asexual blood stage (e.g. major merozoite surface protein (MSP-1); ring-infected erythrocyte surface antigen (RESA)). Malaria vaccine developments have been reviewed by Tsuji and Zavala (2001) and Moorthy et al. (2004).

A synthetic immunodominant repeat sequence, derived from the *P. falciparum* CSP, conjugated to TT, induced antibodies crossreacting with the parasite surface and neutralizing its infectivity in vitro (Zavala et al. 1985). This peptide conjugate proved its safety and immunogenicity in phase I and II clinical trials where the majority of recipients seroconverted. One of three challenged vaccinees was totally protected and in the others the infection was delayed and/or reduced (Herrington et al. 1987). Significant T-cell responses to the coupled peptide were reported which may play a role in priming for protection (Etlinger et al. 1988). In another trial, however, the clinical efficacy of the conjugate was substantially lower and only one of seven vaccinees was protected against a sporozoite challenge (Herrington et al. 1990). MAPs, containing BCEs and TCEs, significantly improved immunogenicity (Tam et al. 1990). MAPs induced higher titers of neutralizing antibodies in mice (Joshi et al. 2001) and, in combination with alum and saponin QS21, in monkeys (Moreno et al. 1999) and humans (Nardin et al. 2000). Novel multiepitope polyoxime constructs containing the CSP repeat epitope, a CSP-derived universal TCE and the built-in adjuvant P3C, induced high antibody levels in human volunteers of diverse HLA types (Nardin et al. 2001).

A repeat domain epitope derived from *P. berghei* CSP induced high serum titers of protective antibody responses in mice when administered as TT conjugates. In these constructs, the orientation of the conjugated peptide, as well as the peptide:carrier ratio, was critical for protection (Zavala et al. 1987). Only BSA conjugates with a high enough peptide load achieved total protection in animals (Reed et al. 1996). Multiple antigen delivery systems containing *P. berghei* CSP-derived BCEs and TCEs induced protective immune responses in mice when combined with CFA (Tam et al. 1990) or detoxified lipopolysaccharide (RaLPS) (Reed et al. 1997). Despite the presence of a *P. yoelii* CSP-derived BCE in the multiple antigen constructs of Reed et al. (1997), protection was weak against *P. berghei* and negative against *P. yoelii*. However, when delivered in a recombinant HBV nucleocapsid antigen (HBcAg), the *P. yoelii* CSP-derived BCE induced protective immune responses in mice (Schodel et al. 1997) and results were promising in preclinical trials in primates (Birkett et al. 2002).

Multiple antigen constructs (MAC) containing a BCE from the *P. vivax* CSP repeat region and a promiscuous TCE from TT induced a protective immune response in monkeys when administered with alum or RaLPS (Yang et al. 1997).

LSA-3 is a highly conserved pre-erythrocytic antigen and a promising vaccine candidate (Perlaza et al. 2001). A 26-residue sequence of this protein induced strong B, Th cell, and CTL responses in chimpanzees when delivered as palmitoyl-conjugated lipopeptides (BenMohamed et al. 1997). Protective immune responses were achieved with a combination of lipopeptides (Daubersies et al. 2000).

Several peptides derived from the merozoite MSP-1 antigen were included in conjugates using BSA or TT as carriers (Berzins et al. 1986) or, more recently, in 'double dimer constructs' (Rivera et al. 2002). These peptides induce antibodies that partially protected monkeys against a challenge infection. Peptides of another well-characterized asexual blood stage antigen, the RESA protein, coupled to TT or KLH, inhibited merozoite reinvasion of erythrocytes in vitro (Cheung et al. 1986) and gave partial protection in monkeys (Patarroyo et al. 1987). Similarly, peptide conjugates from other merozoite stage antigens, such as Pf55 and Pf35, provided partial protection in monkeys and even complete protection when three conjugates were combined (Patarroyo et al. 1987).

Multicomponent and multistage strategies have been considered in order to induce several lines of defense against the different stages of its life cycle. Patarroyo and colleagues developed a synthetic hybrid polymer, containing the peptide sequences derived from MSP-1, Pf55, and Pf35, and repeat sequences from CSP, which was further polymerized using cysteine residues at its N- and C-terminal ends to result in a high-molecular-weight synthetic protein (150 000) inducing protective immune responses in monkeys (Patarroyo et al. 1988; Rodriguez et al. 1990; Ruebush et al. 1990). Very promising results were initially obtained with this fully synthetic protein termed 'SPf66', in early clinical trials, when administered together with alum as adjuvant: delay or even complete suppression of parasitemia was observed in immunized human volunteers (Patarroyo et al. 1988; Amador et al. 1992a, b; Valero et al. 1993). Antibodies induced in humans markedly inhibited parasite growth in vitro (Salcedo et al. 1991). The vaccine was shown to be highly immunogenic and safe in children aged 1–14 years (Patarroyo et al. 1992). Efficacy of up to 80 percent was observed (Amador et al. 1992b). However, the efficacies reported subsequently in larger field trials were consistently below 40 percent (Valero et al. 1993, 1996) and in a study in northern Thailand, an area with a high *P. falciparum* attack rate, no protection was observed (Nosten et al. 1996). In a different approach Shi and colleagues used a recombinant polyepitope containing twelve BCE, six T-helper epitopes, and three CTL epitopes derived from nine stage-specific *P. falciparum* antigens expressed in the baculovirus system (Shi et al. 1999). This polyepitope induced antibodies cross-reacting with the different stages of the parasite and neutralizing parasite activity in vitro (Shi et al. 1999). Recombinant polyepitope constructs based on CTL epitopes are being further explored with encouraging results (Tsuji and Zavala 2001).

SCHISTOSOMIASIS

Schistosomes are parasitic trematodes causing chronic disease in an estimated 200 million people worldwide. Infections in humans are mostly caused by one of the three helminth species *Schistosoma manson i*, *S. haematobium*, and *S. japonicum*, and candidate vaccines are currently being investigated in clinical trials (Capron et al. 2002). Several antigens or fragments derived from them, e.g. 9B (Tarrab-Hazdai et al. 1998), P28-1 (Wolowczuk et al. 1989), Sm23 (Reynolds et al. 1992), triose phosphate isomerase (TPI) (Reynolds et al. 1994), Sm14 (Tendler et al. 1996), and glutathione-*S*-transferase (Sm28-GST) (Ferru et al. 1997) have been identified as targets of specific B-cell and Th-cell responses. Early work on synthetic peptide vaccines against schistosomiasis has been discussed by Harn et al. (1995). In more recent studies a polymer of 14 peptides derived from the 9B antigen, conjugated to BSA, induced an immune response that was able to reduce significantly the worm burden after challenge in a murine model (Tarrab-Hazdai et al. 1998). Protective immune responses were also observed after intranasal immunization with a recombinant salmonella flagellin protein carrying this 9B epitope sequence (Ben-Yedidia et al. 1999). By screening a solid-phase octamer library against a 9B-specific mAb, four peptide mimotopes were identified, one of which induced a protective immune response (Arnon et al. 2000). It is noteworthy that protection against *S. mansoni* challenge was also obtained after immunization with two unconjugated peptides (derived from the Sm14 antigen) in the presence of the adjuvant system monophosphoryl lipid A/trehalose dicorynomycolate (MPL-TDM) (Vilar et al. 2003). Interestingly, these Sm14-derived epitopes cross-protected mice against a challenge with *Fasciola hepatica*, a helminth affecting sheep and cattle (Vilar et al. 2003). A multiepitope approach, combining 10 different epitopes of various *S. mansoni* antigens, was investigated using DNA and recombinant protein immunization. However, none of the tested constructs induced a protective response (Yang et al. 2000).

CYSTICERCOSIS

Taenia solium, a parasitic tapeworm causing cysticercosis, is highly prevalent in humans and pigs in Latin America, Asia, and Africa, and has serious health and economic consequences. Experimental vaccines for use in pigs, the obligatory intermediate host, are currently under development and include a peptide-based approach (reviewed by Sciutto et al. 2002).

Four recombinant antigens (KETc1, -4, -7, and -12) expressed during the cysticercus stage of both *T. solium* and *T. crassiceps*, a cestode causing murine cysticercosis, confer different levels of protection in immunized mice (Manoutcharian et al. 1996). A synthetic 18-residue peptide GK-1, derived from the KETc7 protein and emulsified in saponin, induces antibodies crossreacting with the cognate antigen without the use of a carrier protein (Toledo et al. 1999). It is noteworthy that this

GK-1 peptide contains at least one TCE, which was demonstrated by its ability to stimulate proliferation of $CD8^+$ and to a lesser extent $CD4^+$ T cells. GK-1-induced immunity only partially protected against a challenge infection with *T. crassiceps* and this did not improve when the peptide was delivered as MAP or coupled to BSA (Toledo et al. 1999). Similarly, two polymeric peptides of 13 and 9 residues, derived from the KETc1 and -12 antigens, induced B-cell and T-cell responses, partially protecting mice against cysticercosis caused by *T. crassiceps* (Toledo et al. 2001). In a controlled field trial, immunization of piglets with a combination of the unconjugated peptides KETc1, -7, and -12 with saponin decreased the total number of viable *T. solium* cysticerci by almost 98 percent and the prevalence of cysticercosis among immunized animals by more than half (Huerta et al. 2001).

Contraception

A vaccine providing safe, inexpensive, and reversible contraception would greatly help to regulate the world's growing population (reviewed by Aitken 2002). A peptide approach would at least be inexpensive, reversible after 1–2 years, and would not require a cold chain.

A C-terminal peptide of human chorionic hormone (hCG), an essential hormone during pregnancy, coupled to TT, induced high titers of antibodies, successfully reducing fertility in female baboons (Stevens et al. 1981a). Further studies in mice, rabbits, and baboons led to the formulation of a vaccine based on the water-soluble synthetic adjuvant, *N*-acetylglucosamine-3-yl-acetyl-l-alanyl-d-isoglutamine (CGP-11637) suitable for use in humans (Stevens et al. 1981b). In clinical trials, hCG-crossreactive antibodies were observed, which were thought to neutralize the biological activity of hCG, but definitive proof of a contraception was not obtained in this study (Jones et al. 1988). The low immunogenicity of this hCG peptide was overcome by immunizing with the entire β-subunit of hCG and prevention of pregnancy was shown in clinical trials (Talwar 1999). The luteinizing hormone-releasing hormone (LHRH) is a short decapeptide hormone secreted by the hypothalamus. Branched peptide constructs containing the LHRH peptide and a T-helper cell epitope (ThCE) induced sterilizing antibodies in female mice (Ghosh and Jackson 1999).

A synthetic BCE of the zona pellucida glycoprotein ZP3, either conjugated to KLH (Millar et al. 1989) or delivered as a chimeric peptide containing a foreign promiscuous TCE (Lou et al. 1995; Sadler et al. 1999), induced antibodies in mice crossreacting with the cognate protein, providing a long-term, but reversible, contraception without impairment of normal ovarian functions. Immunocontraception was also produced in female macaques after administration of conjugates with coupled human and macaque ZP3 peptides (Mahi-Brown and Moran 1995; Mahi-Brown 1996). Antibodies inhibiting human sperm binding to oocytes in vitro were obtained using chimeric TCE–BCE peptides in macaques (Bagavant et al. 1997) and common marmosets, but the antibodies did not reduce fertility in a primate model (Paterson et al. 1999, 2002). Antibodies targeting an epitope located on the human sperm antigen lactate dehydrogenase (LDH)-C_4 have been induced in baboons using peptide conjugates and chimeric peptides (O'Hern et al. 1995, 1997). Fertility in immunized animals was reduced by 70 percent and the contraceptive effect lasted for almost a year. The same epitope in chimeric peptides induced significant contraception in mice (Sadler et al. 1999). Recently, a novel peptide epitope (YLP12) was identified on human sperm, eliciting long-lasting sperm-specific antibodies that assured contraception in female mice when conjugated to CTB and administered intranasally (Naz and Chauhan 2002; Naz 2004). Fertility was fully restored after 10 months when the antibody titers had fallen below a certain threshold.

Immunocastration has been developed as an economical alternative to surgical castration of male pigs to prevent the growth of testes and the production of male sexual steroid hormones, which is associated with an unappealing odor of the meat. Immunocastration was obtained in male pigs after CFA-adjuvanted immunization with peptides derived from gonadotropin-releasing hormone (GnRH) and conjugated to KLH or OVA (Meloen et al. 1994) or ISCOMs (Beekman et al. 1999). Similarly high responding rates were obtained with low doses of conjugated double-dimer peptides mixed with a mild oil adjuvant (Specol; Oonk et al. 1998; X.Y. Zeng et al. 2001). With the encouraging results and the specific advantages of a peptide vaccine, this approach may become a truly inexpensive alternative to current contraceptive drugs.

Alzheimer's disease

Alzheimer's disease, the most common cause of dementing disorders in elderly people, causes progressive loss of central nervous functions. Pathogenesis involves the overproduction of the 42-residue amyloid-β peptide ($A\beta_{42}$) derived from the amyloid precursor protein (APP), progressive accumulation of $A\beta_{42}$ in extracellular plaques within the cerebral cortex and the hippocampus (Reilly et al. 2003), followed by neurodegeneration (Selkoe 1999). The progress of and drawbacks in antibodies as therapeutic agents in Alzheimer's disease have been extensively discussed by Morgan (2003) and Solomon (2002).

Transgenic mouse models have been used to investigate the possibility of therapeutic immunization against Alzheimer's disease (Games et al. 1995). Immunization with the synthetic $A\beta_{42}$-induced $A\beta_{42}$-specific antibodies,

which prevented the development of β-amyloid plaque and Alzheimer's disease-type neuropathologies in animals immunized at a young age (Schenk et al. 1999). Moreover, these antibodies greatly reduced progressive degeneration and even cleared pre-existing plaques of $A\beta_{42}$ deposits in older animals (Schenk et al. 1999). Furthermore, $A\beta_{42}$ immunization prevented learning and age-related memory defects normally developing in transgenic mice (Janus et al. 2000; Morgan et al. 2000). Significant decrease in the cerebral β-amyloid plaque burden was also obtained in mice after intranasal administration of synthetic $A\beta_{42}$ using LT as adjuvant (Weiner et al. 2000; Lemere et al. 2001). In vitro studies revealed that mAbs specific for a short $A\beta_{42}$ N-terminal fragment prevented fibrillar aggregation and $A\beta_{42}$-mediated neurotoxicity in a concentration-dependent manner (Solomon et al. 1997). Immunization of mice using a recombinant filamentous phage displaying an N-terminal derived tetramer peptide sequence induced antibodies that exhibited in vitro anti-aggregating properties and neutralizing $A\beta_{42}$-related toxicity (Frenkel et al. 2001, 2003). This phage also markedly reduced the number of plaques in the brain of transgenic mice (Frenkel et al. 2003). Similar protective in vivo effects were obtained after immunization with a modified $A\beta_{42}$-derived, polylysine peptide (Sigurdsson et al. 2001). Furthermore, low antibody titers and self-tolerance were proposed to result primarily from inadequate T-cell help, which could be overcome by using palmitoylated $A\beta_{42}$ reconstituted in liposomes–lipid A (Nicolau et al. 2002) or by conjugating a short $A\beta_{42}$-derived polymer of 15 residues to BSA (Monsonego et al. 2001). However, immunization with conjugated, short, serum amyloid protein-derived peptides did not protect mice against β-amyloid plaque deposits (Schenk et al. 1999). Antibodies against plaque components themselves may not be sufficient to prevent plaque aggregation and antibodies targeting specifically the $A\beta_{42}$ seem to be required for preventing disease.

A phase I study showed that immunization with the synthetic $A\beta_{42}$ was well tolerated and some patients developed $A\beta_{42}$-specific antibodies (Schenk 2002). However, phase IIa trials had to be discontinued because of several reports of inflammatory symptoms of the central nervous system which resembled encephalitis or meningitis (Check 2002). Autopsy of a brain from a treated patient provided astonishing evidence of how anti-$A\beta_{42}$ antibodies efficiently cleared $A\beta_{42}$ deposits in the cerebral cortex (Nicoll et al. 2003). Intriguing parallels between the rare cerebral amyloid angiopathy-associated inflammation and the vaccine-related encephalitis suggests that the vaccine-mediated inflammatory response was directed not only against the $A\beta_{42}$ plaques but also against vascular amyloid (Greenberg et al. 2003; Nicoll et al. 2003; Robinson et al. 2003). With more refined immunotherapeutic approaches, which will avoid autoimmune and acute neuroinflammatory responses (Robinson et al. 2003; Weller and Nicoll 2003), peptide-based immunotherapy against Alzheimer's disease may become a realistic option.

BCE peptide vaccines against cancer

Although most studies with peptide vaccines against tumors target CTLs (see later), interesting results have also been obtained with peptides eliciting anti-tumor antibodies, e.g. Kaumaya and colleagues (Dakappagari et al. 2000) developed a chimeric HER-2 BCE vaccine in mice transgenic for a homolog of human HER-2. These mice developed mammary tumors that resembled human breast cancer. Peptides corresponding to predicted BCEs were co-linearly synthesized with a promiscuous TCE of MV, induced antibodies in rabbits that crossreacted and interrupted the development of mammary tumors in the above transgenic mouse model, and mediated killing of human tumor cells in vitro (Dakappagari et al. 2000). Table 1 shows that such antibodies against breast cancer and others have also been elicited in humans by immunization with peptides derived from different tumor-associated antigens (TAA). In the case of B-cell lymphomas, peptides inducing anti-idiotype responses resulted in a clinical response in most patients (Hsu et al. 1996; Bendandi et al. 1999).

PEPTIDE-BASED VACCINES AGAINST TCES

Although peptides have also been used to induce protective CTLs against infectious and other disease, the focus of this section is on CTLs of malignant tumors.

Tumor immunology and peptides

A number of reviews have been published on different aspects of synthetic peptides as cancer vaccines (Mayordomo et al. 1996; Slingluff 1996; Olive et al. 2001; Buteau et al. 2002; Machiels et al. 2002; Parmiani et al. 2002a, b; Sundaram et al. 2002). Some authors have concentrated on certain tumors, or tumor antigens including melanoma (Mocellin et al. 2003), HPV-associated malignancies (Fausch et al. 2003), and Her-2/neu (Correa and Plunkett 2001; Disis et al. 2001; Knutson and Disis 2001; Salit et al. 2002).

Early studies showed that the injection of tumor-derived material in animals or even cancer patients limited tumor growth. With the discovery of TAAs it became possible to investigate the immune response against cancer (reviewed by Herlyn and Koprowski 1988; Schreiber et al. 1988; Urban and Schreiber 1992; Boon et al. 1994). These studies showed that T cells mediate the principal effector mechanisms against tumors, although the humoral response as demonstrated

by therapeutic monoclonal antibodies such as trastuzumab (Herceptin, Baselga 2001), rituximab (Rituxan, Davis et al. 1999; Huhn et al. 2001), and peptide-specific antibodies (see Table 1) must not be underestimated.

Unlike B cells (see earlier), T cells do not recognize intact proteins but rather MHC-bound antigen-derived peptides. These peptides are generated during antigen processing and are presented by MHC class I or II molecules to $CD8^+$ or $CD4^+$ T cells. Normally CTL epitopes originate from intracellular proteins degraded in the cytosol by the proteasome and carried by specialized transporters (TAPs) into the endoplasmic reticulum, where they bind to MHCI to be taxied to the cell surface for a date with $CD8^+$ T cells. In contrast, $CD4^+$-restricted epitopes originate from exogenous proteins taken up and degraded in phagolysosomes into peptides that co-localize with MHCII, which shuttles them back to the cell surface, where they meet with $CD4^+$ T cells. MHC molecules fix peptides in an extended conformation and synthetic peptides are undistinguishable from natural peptides.

T cells specific for TAAs were found in many cancer patients but also in healthy donors. In healthy individuals, frequencies of such CTLs seem to be lower (Marincola et al. 1996; Altieri et al. 1999; Nagorsen et al. 2000; Andersen et al. 2001) and of a different phenotype. In healthy donors these were of the $CD45RO^+$ naive T-cell subset, whereas in melanoma patients peptide-specific CTL precursors were of the functionally distinct $CD45RO^+$, $CCR7^+$ memory phenotype (D'Souza et al. 1998; Anichini et al. 1999; Dunbar et al. 2000).

In clinical trials in tumor patients, promising results such as full or partial remission have been largely attributed to the induction of $CD8^+$ MHCI-restricted CTLs. Many TAA-derived MHCI-restricted peptides are recognized by tumor-specific CTLs at both the induction and the effector stage (see Table 4; Jager et al. 2001).
In addition, MHCII-restricted ThCEs of a number of TAAs have been identified (Topalian et al. 1996; Manici et al. 1999; Pieper et al. 1999; Wang et al. 1999b; Chiari et al. 2000; Renkvist et al. 2001). In the first application of a peptide vaccine in humans, HBV-negative volunteers were immunized with a lipopeptide construct containing an HLA-A*0201-restricted peptide, a pan-class II-binding peptide, and palmitic acid tails. CTLs were induced that lysed syngeneic HBV-infected target cells in vitro (Vitiello et al. 1995). Cytotoxic TCEs restricted by some of the more frequent MHCI alleles have been identified for an increasing number of TAAs (reviewed by Maeurer et al. 1996). Peptides derived from a variety of TAAs have sometimes induced vigorous responses against tumors. Regression of primary tumors and metastasis were seen using a variety of different immunization protocols.

However, to measure the success of tumor immunization, the identification of surrogate in vitro read-outs, which correlate and may even predict clinical outcome, is of paramount importance. Besides conventional assays such as CTL and cytokine assays, increasingly sophisticated reagents based on synthetic peptides such as a MHC–tetramer (www.niaid.nih.gov/reposit/tetramer/index.html) and MHC–Streptamer complexes (Knabel et al. 2002, www.iba-go.com) become commercially available to study and even isolate peptide-specific T cells for functional assays.

Identification of CTL epitopes

Synthetic peptides have been powerful tools to identify class II- and I-restricted TCEs by systematic screening in functional assays. MHC-bound peptides eluted directly from tumor material of patients were identified on the basis of their mass and partial sequence by highly sensitive tandem mass spectrometry (Hunt et al. 1992). Increasingly refined prediction algorithms support these studies since the structural basis of MHC-peptide binding became understood (Pamer et al. 1991). Pool sequencing of MHC-eluted peptides (Rotzschke et al. 1990; Falk et al. 1991) has revealed that peptides bind to MHCI via an allele-specific consensus motif of anchor residues. Thus, MHC molecules encoded by different gene loci and different haplotypes bind their own distinct (but sometimes overlapping) family of peptides, usually with eight to ten amino acids (for a review, see Rammensee 1995; Rammensee et al. 1995, 1997). Interactive websites (www.syfpeithi.bmi-heidelberg.com, www.bimas.dcrt.nih.gov/molbio/index.html) identify peptides within a submitted antigen sequence that bind to a given MHC. Other consensus motifs have been identified to predict peptides surviving antigen processing (Nussbaum et al. 1998, 2001; Kuttler et al. 2000) and contributed to interactive websites (www.paproc.de, www.mpiib-berlin.mpg.de/MAPPP) to predict TCEs. In the light of these developments, prediction algorithms based on structural considerations such as amphipathic helices (DeLisi and Berzofsky 1985) must now be considered obsolete.

The rationale of peptide-based vaccines against cancer TCEs

Cancer vaccines can be based on whole cancer cells, TAAs, or peptide fragments of TAAs. Whole tumor cells of a good quality and quantity can be obtained only from large surgical tumors. Early detection of small tumors and tumor regression under conventional therapy severely limits the availability of tumor material. Immunization as an adjuvant therapy against (minimal) residual disease would also suffer from lack of tumor material. Furthermore, the preparation of a vaccine from an ex vivo tumor is laborious and expensive. Although recombinant TAAs may seem like obvious

antigens of tumor vaccines, most TAAs are not tumor specific. TAAs often resemble antigen with limited expression in healthy tissues and may succumb to self/nonself discrimination. In some cases, such as Her-2/neu antigen, peptides elicited immunity when whole proteins were unable to do so (Disis et al. 1996). In humans, delivery systems to induce CTL responses such as replicating or nonreplicating viral vectors, DNA, or liphophilic adjuvants are often only poorly immunogenic or are not safe in immunosuppressed tumor patients. Peptides, which can be produced easily and in large quantities, are more than an alternative of convenience; in fact, peptides derived from TAAs are the true antigens recognized by the T cells. In contrast to proteins, peptides can deliver epitopes in high molar concentrations (directly in vivo, or by dendritic cell (DC) pulsing in vitro) to improve MHC loading, although high concentrations have sometimes led to tolerization (Aichele et al. 1995; Toes et al. 1996a, b).

Increasing the immunogenicity of peptide tumor vaccines

Although clinical trials demonstrated that peptides induce CTLs, their immunogenicity in cancer patients is often too low to clear the tumor and even partial tumor regression is unreliable (Marchand et al. 1999). To enhance the immunogenicity of TAA-derived peptides numerous strategies have been developed.

CD4 T-CELL HELP

Activated $CD4^+$ T cells help to initiate and amplify the CTL response. Class II-restricted TCEs have been identified from a number of tumor antigens (Jager et al. 2000b; Zarour et al. 2000; G. Zeng et al. 2001). The identification of class II-restricted epitopes is complicated by the open-ended binding groove of MHCII which accommodates peptides that are much less well defined in terms of length (Chicz et al. 1992; Rammensee et al. 1995), anchor positions (Rammensee et al. 1997), and processing (Robinson and Delvig 2002). Some studies have included TAA-derived class II-restricted TCEs in peptide vaccine trials (see Table 4).
If these may be more efficient, they need to be defined for each TAA and the MHC context of every individual patient. Alternately, it has been proposed to include promiscuous helper TCEs that bind to many class II molecules (see earlier). These TCEs are normally derived from tumor-unrelated antigens such as TT (Kaumaya et al. 1993; Dakappagari et al. 2000; Slingluff et al. 2001) or they are totally artificial such as the broadly reactive PADRE peptide (Weber et al. 1999) (see Table 3). Despite some exceptions (Phan et al. 2003), clinical studies seem to suggest that the inclusion of a class II-restricted helper TCE may improve the level and duration of anti-tumor CTL activity, although few systematic studies have been reported.

MODIFIED PEPTIDES

HLA–peptide–T-cell receptor (TCR) complexes can be optimized for improved T-cell activation by peptide modifications (Chen et al. 1996), e.g. modification of MHC-binding anchor residues of peptides of the Melan-A/MART-1(27–35), the gp100 (209–217), Her2/neu, or folate-binding protein resulted in improved peptide–HLA binding and stability (Fisk et al. 1995; Parkhurst et al. 1996; Valmori et al. 1998; Tourdot et al. 2000). By mutating peptide residues of epitopes of Melan-A/MART-1(27–35), carcinoembryonic antigen (CEA) and NY-ESO-1 signaling of TCR and T-cell stimulation was enhanced (Rivoltini et al. 1999; Salazar et al. 2000). Systematic positional scanning with sets of peptide libraries, each containing in each position every amino acid flanked by undefined amino acids, has been performed to improve peptide interactions within the MHC–TCR complex (Fleckenstein et al. 1996; Wiesmüller et al. 2001). Peptide analogs with improved properties have been defined for Melan-A-specific CTL clones (Pinilla et al. 1999, 2001). Other modifications including terminal acetylation or amidation may protect against premature proteolytic degradation in vivo (Brinckerhoff et al. 1999).

PEPTIDE FORMULATIONS

Alum is the only adjuvant licensed for human use, with decades of experience. However, this adjuvant is well known to induce a Th2-biased response, which elicits a humoral rather than a CTL response. More recently virosomes (influenza virus-like particles) have been licensed (Moser et al. 2003) but so far this has not been included in cancer peptide vaccine trials. Thus, peptide vaccine trials used either no adjuvants (see Table 4) or experimental adjuvants or cytokines (reviewed by Machiels et al. 2002). Although, in early studies, peptides without adjuvant have led to complete remission of metastatic tumors (Marchand et al. 1995), immunization regimens reinforced with adjuvants and cytokines tend to improve the immune response and, sometimes, the clinical outcome. Some adjuvants (Montanide ISA-51, QS-21) induced specific CTLs in a few high-risk resected melanoma patients associated with a 75 percent 5-year survival rate (Slingluff et al. 2001). The combination of different adjuvant strategies may have some benefit, e.g. low-dose IL-12 improved the immune response of IFA-emulsified peptides, but without clinical improvement (Lee et al. 2001). The modified gp100 peptide g209-2M, combined with IFA and high doses of IL-2 (but not without IFA or with granulocyte–macrophage colony-stimulating factor (GM-CSF)), showed a good clinical response (Rosenberg et al. 1999). Besides soluble or lipophilic adjuvants, other

formulations include biodegradable beads targeting peptides to antigen-presenting cells (Frangione-Beebe et al. 2000, 2001). Table 4 shows many examples of adjuvants used in clinical trials, but patient groups and interventions are difficult to compare in a systematic way. In these trials side effects were attributed mostly to the adjuvants used (Goydos et al. 1996), rather than the peptides that normally show no or only mild toxicities.

DENDRITIC CELLS-PRESENTED PEPTIDES

Dendritic cells (DC) are the most potent antigen-presenting cells and they effectively induce CTL responses (reviewed by Banchereau et al. 2000; Guermonprez et al. 2002). They can be obtained from the patient's blood or bone marrow and expanded to large numbers in vitro (reviewed by Mayordomo et al. 1997). Peptides can be loaded on to autologous differentiated DCs, which are returned to the patient to induce tumor-specific T cells (for a review, see Parmiani et al. 2002a, b). The route of administration (e.g. intravenously or subcutaneously) of peptide-loaded DCs seemed to be important, perhaps because of differential homing of the DCs into regional lymph nodes or the spleen (Eggert et al. 1999). Co-administration of cytokines such as IL-12 (Grohmann et al. 1997a, b) or pulsing DCs with mixtures of CD4- and CD8-restricted TCEs improved results. Overall, this very fastidious procedure gave mixed and sometimes very encouraging results (Banchereau et al. 2001; Thurner et al. 1999; Nestle et al. 1998; Murphy et al. 1999b; Kugler et al. 2000). TAA-peptide-loaded DC vaccines seem to generate CTL responses, more often and more efficiently, than peptide with or without IFA, but clinical responses remained low. A notable exception was the anti-idiotype vaccine against follicular B-cell lymphoma which gave, in two of four patients, a complete and, in one, a partial clinical response (Hsu et al. 1996). Follow-up studies with GM-CSF as an adjuvant instead of DCs gave a tumor-specific T-cell response and a complete and durable molecular remission in eight of eleven patients with minimal residual disease (Bendandi et al. 1999).

Alternate delivery of peptide vaccines

To improve the immune response in the cancer patient, multiple CTL epitopes of one or several TAAs combined with or without BCEs and aided by vigorous T-helper epitopes may be required. A number of strategies have been proposed to bring together peptides of different epitopes covalently. The synthesis of constructs consisting of longer or multiple peptides rivals recombinant strategies. Numerous strategies based on recombinant viruses, DNA, or RNA have been developed to deliver oligonucleotides encoding peptides directly into host cells via different invasive or noninvasive routes (reviewed by Arnon and Ben-Yedidia 2003). The use of synthetic TCE vaccines consisting of one or a few peptides is limited by MHC polymorphism. To overcome these limitations peptides have been fused genetically to form polyepitopes (reviewed by Suhrbier 2002). These were either produced as recombinant proteins fusing, e.g. a large number of CTL epitopes of Epstein–Barr virus, or as recombinant viral vectors (modified vaccinia Ankara (MVA)), or DNA in the case of HIV (Hanke and McMichael 2000; Wee et al. 2002) and *Plasmodium falciparum* epitopes (Gilbert et al. 1997; Richie and Saul 2002). Polyepitopes were also used to pulse DCs to immunize against malignant melanoma (Smith et al. 2001) and breast cancer (Scardino et al. 2001). A detailed discussion of these recombinant polyepitope strategies is beyond the scope of this review.

Synthetic TCE peptide vaccines against tumor viruses

Prophylactic immunization against viruses with MHC-restricted peptides is not practical for obvious reasons. However, some viruses are responsible for the induction of human cancers, including hepatocellular carcinoma, cervical carcinoma, and others. With the long tradition of immunization against viruses it was logical that the first peptide immunization against cancer was a viral peptide derived from HBV (Vitiello et al. 1995), although most progress has been reported with peptide immunization against HPV (reviewed by Fausch et al. 2003). Early animal studies showed that peptides derived from HPV protected mice against a HPV protein-expressing tumor both prophylactically and curatively (Feltkamp et al. 1993; Zwaveling et al. 2002). With the identification of HLA-A2-restricted HPV16 and HPV18 peptides, which induced CTLs, clinical trials became possible (Feltkamp et al. 1995). These were further encouraged by observations that class II-restricted memory responses against E6 and E7, the only HPV proteins expressed in cervical carcinoma, were found in patients but not in healthy volunteers (Da Silva et al. 2001). In a clinical trial with advanced cancer patients, two HPV-E7 peptides and a T-helper peptide in Montanide ISA51 induced a T-helper response in four of twelve patients but no E7-specific response (Ressing et al. 2000). In another trial with late-stage tumors, a lipidated E7 peptide induced a specific CTL response but no clinical response (Steller et al. 1998). Ten of sixteen patients with high-grade tumors showed CTL responses and partial or complete remission (Muderspach et al. 2000).

Peptides as cancer vaccines: Concluding remarks

The use of synthetic peptides has resulted in significant advances in the understanding of the immune response

at the epitope level. They have also been shown to induce vigorous CTL responses, which sometimes correlated with partial or even complete tumor regression. In some cases this response was long lasting. However, a number of challenges must be tackled to turn peptides into effective anti-cancer vaccines (Buteau et al. 2002). Heterogeneity and small numbers of patients, immunization regimens that are difficult to compare, and variability in monitoring clinical and immunological outcome are only some of the factors that complicate comparisons between different clinical trials. Clinical trials comparing different parameters are therefore warranted, each with sufficient numbers of patients. Some authors believe that, before any further progress can be made, the understanding of the mechanisms involved in tumor killing needs to improve (Mocellin et al. 2003), e.g. Rosenberg et al. (1998) observed that co-administration of IL-2 with gp100 peptides dramatically enhanced tumor response but reduced peptide-specific CTL response from 10 of 11 to 3 of 19 (see Table 4). This sheds serious doubts on the utility of CTL assays as an objective parameter to monitor tumor cytotoxicity and more appropriate assays may be required for immune monitoring (Machiels et al. 2002). It also seems important to complement in vitro cytotoxicity with a detailed phenotyping of CTLs. More molecular studies are also necessary to understand the mechanism by which the tumor undermines the development of an efficient immune response and escapes effector mechanisms (Marincola et al. 2000).

Mechanisms that lead to epitope-specific T-cell tolerization, instead of T-cell activation, need to be explored (Aichele et al. 1995; Toes et al. 1996a, b). Immunization with certain peptides can lead to tolerance in protocols that induce protection with other peptides (Feltkamp et al. 1993; Mandelboim et al. 1994; Melief and Kast 1994, 1995; Toes et al. 1996b). CTL epitopes have so far been identified for only a few HLA molecules. Although it can be expected that, after proof of the concept, peptides restricted by most MHC molecules would be identified, MHC polymorphism severely limits peptide immunization studies in humans. MHC transgenic mice could help but experimental tumors poorly reflect human tumors. On the other hand, polyepitope vaccines based on (genetically) fused peptides could overcome some of these problems, although some regulatory issues remain unsolved (Suhrbier 2002). With few exceptions clinical response was below 30 percent. Although this seems low, many of the studies were done in patients with advanced stage disease and this response has been obtained with minimal side effects. Peptide immunization is probably more efficient in low-grade tumor patients with an intact immune system. Thus, peptide immunization could be a treatment of choice in the case of minimal residual disease when the immune system has recovered from suppression caused by the tumor and aggressive therapy and when tolerance for side effects is low (Bendandi et al. 1999; Jager et al. 1999). The demonstration of a benefit would, however, take many years of observation. Immunization protocols are far from being optimal and most results need to be confirmed in large prospective clinical trials, to systematically compare different TAAs, epitopes, peptide formulations, adjuvants, and routes.

FINAL COMMENTS: DIFFICULTIES AND MISCONCEPTIONS

The main difficulty in developing a peptide-vaccine based on a BCE is its conformational diversity. Even in the case of a peptide inducing (low) neutralizing antibodies, chemical stabilization of the proper conformation should be considered. In this respect, most peptides are perhaps only lead structures that guide the development of structurally stabilized antigens, rather than being the antigens themselves.

Many of the obstacles to the development of TCE-based peptide vaccines against tumors are inherent to tumor immunology and are not particular to peptide vaccines. In this respect, peptides as tumor vaccines have done very well. With the ease of immunization with peptides and the low levels of side effects, their potential should be more systematically explored in minimal residual disease or in patients in remission with a high risk of relapse.

Peptide vaccines tend to suffer from an inherent contradiction: low cost, biological safety, and chemical and thermal stability are mostly features of prophylactic vaccines, meant to protect healthy vaccinees against pathogens. Such prophylactic vaccines, however, do not normally require an epitope-based approach. In contrast, in therapeutic vaccines, in particular against neoplasms, allergies, and autoimmune disease where epitope-based strategies may be important, features such as low cost, safety, and stability are much less relevant.

To judge the success or failure of experimental peptide vaccines, a comparison with other vaccine strategies is warranted. No peptide vaccine is licensed so far, but also only a few recombinant vaccines had reached the (American) market by 2001 (HBV, cholera, pertussis) without being subsequently withdrawn (*Borrelia*, rotavirus). The US Institute of Medicine estimated that, of the more than 30 new vaccines that will reach the market by 2010, about 25 percent are obtained by recombinant technology, but none will be peptide based (Landry 2002).

Live vaccine carriers

GORDON DOUGAN, RICHARD J. ASPINALL, FRANCES BOWE AND LILJANA PETROVSKA

Live vaccines are inherently immunogenic 1
Examples of viral and bacterial vectors 1
Enhanced targeting of the immune system with live vectors 7
Influence of route of delivery 8
Conclusions 9
Acknowledgments 9
References 9

Since the first recognized vaccinations performed by Edward Jenner the use of live attenuated microorganisms as vaccine components has been a practical option. Live vaccines often offer the advantage over nonliving vaccines of enhanced immunogenicity. In the early days of vaccine development when investigators used essentially empirical approaches, live vaccines were often a favored practical route because there is no requirement for the identification of component protective antigens. Also, dead whole cells were often either reactogenic or nonprotective. Although live approaches were often useful for inducing immunity, old-style live vaccines ran the risk of reversion to virulence to the extent that, over the years, there were many accidents with their use. Over the past few decades our ability to manipulate microorganisms using genetic approaches has opened up the option of rational attenuation. This is the so-called designer approach to live vaccine development. Rational attenuation involves the identification and stable inactivation of genes in pathogens that normally contribute to pathogenesis in the host. By knocking out genes that are essential for virulence, but not for life, it is possible selectively to disable pathogens in terms of their ability to cause disease. Theoretically, combinations of attenuating mutations can be employed to optimize both immunogenicity and safety simultaneously. In practice this can be a difficult goal to achieve, particularly if optimization is first attempted in a model rather than the target host. An alternative to rational attenuation is the complete characterization (total sequence) of the genetic content of well-characterized attenuated vaccine strains. Examples here would include various attenuated viruses such as those derived from polio virus and vaccinia or even bacterial vaccine strains. This sequence information can be used as a platform to quality control vaccine lots or provide a basis for further genetic modifications of the vaccine strain.

It is clear from the above that we are now entering a new era of rational live vaccine development. The aim is to develop live vaccines that are safe (nonreverting and nonreactogenic) in both normal and compromised hosts and which are protective following the administration of single vaccine doses. A further attraction of live vaccination is that with some attenuated microorganisms there is the option of immunizing using alternative (intranasal, oral, rectal, etc.) routes of immunization that could avoid the use of needles while offering the potential of inducing local alongside systemic immune responses (see New approaches to vaccine delivery).

Our enhanced ability to manipulate microorganisms genetically has opened up further attractive options for vaccine development. Using recombinant DNA approaches, it is now possible to introduce the genes for heterologous protective vaccine antigens into attenuated microorganisms where the foreign antigens can potentially be expressed as components of the normal proteosome of the host vector. The challenge here is to express the foreign antigen in a stable manner that does not compromise the inherent immunogenicity of the vaccine carrier. Taking this approach it is enticing to imagine the

development of live vaccine strains which, in a single dose, can be used to immunize simultaneously against more than one pathogen. It might be feasible, for example, to immunize in a single vaccine shot against bacterial and viral infectious agents. In fact this goal has now been achieved on many occasions in model hosts such as the mouse (Chatfield et al. 1989), but this technology is proving more difficult to translate into practical immunization formulations for use in humans or target veterinary species (Mastroeni et al. 2001). Part of the problem is the major differences in the way that the immune systems of different hosts respond to vaccines. In addition, individual pathogen strains are often adapted to favor growth in a particular host. Thus, a formulation can be highly immunogenic in one host but poorly immunogenic even in a closely related species. This means that clinical studies can often be disappointing and we need to learn more about how to transfer technology from one species to another. In other words we need better immune correlates. Nevertheless, despite some early problems there is still a great deal of interest and effort in this area, which is the subject of this chapter.

LIVE VACCINES ARE INHERENTLY IMMUNOGENIC

By learning more about the way that the immune system recognizes infectious agents and discriminates between antigens from dangerous sources, such as pathogens from self, it should be possible to understand why live vaccines are immunogenic. Pathogens harbor or synthesize particular degenerate structures that are distinct to themselves and often not natural components of higher eukaryotic hosts. Examples of such molecules include lipopolysaccharide (LPS), flagellins, and double-stranded RNA (dsRNA). Mammalian cells have evolved a series of ligands and receptors that target these pathogen-specific structures. Perhaps the best characterized of these are the Toll receptors which recognize pathogen-associated molecular patterns (PAMP). Binding of the Toll pathway by pathogen components can lead to the activation of the innate immune system and, ultimately, to the amplification of acquired immunity. In fact we now know that many adjuvants act by activating the innate immune system via these types of pathways and that live vectors have inherent immunogenicity because they incorporate PAMPs.

As we move towards pure nonliving vaccines there is a tendency to remove PAMPs from vaccine formulations and consequently to reduce inherent immunogenicity. Adjuvants then have to be added back. We can take advantage of PAMPs for improving vaccine formulations. Even bacterial DNA has a signature that is distinct from eukaryotic DNA. Consequently, bacterial DNA is targeted by Toll-like receptor 9 (TLR9) in both mice (Hemmi et al. 2000) and humans (Takeshita et al. 2001). The technique of so-called DNA immunization (see Naked DNA vaccines) has now been extensively studied since the first demonstration that intramuscular injection of bacterially derived plasmid DNA could result in the expression of an encoded protein (Wolff et al. 1990) capable of eliciting humoral immune responses (Tang et al. 1992), as well as priming antigen-specific cytotoxic T lymphocytes (CTL) (Ulmer et al. 1993). DNA vaccines are effective partly because of the immunostimulatory properties of unmethylated cytidine phosphate–guanosine (CpG) dinucleotide sequences that can upregulate expression of interleukins IL-12, IL-6, and interferon γ (IFN-γ) by macrophages and B cells as well as activating dendritic cells (DC) (Jakob et al. 1998). Immunostimulatory CpG motifs are either absent from eukaryotic DNA or modified. Simply cloning an active CpG site in the correct context into an existing DNA vaccine construct can markedly enhance its efficacy (Sato et al. 1996).

Clearly the combination of PAMPs associated with live vectors enhances immunogenicity but live vaccines are normally much more immunogenic than the equivalent dead microbes. Hence, the fact that live organisms colonize the host using the steps normally associated with infection also clearly enhances their immunogenic potential. Live microorganisms will target and colonize host cells, including immune cells, and antigens will be processed along natural intracellular pathways. It is extremely difficult to reproduce such patterns of immunostimulation and antigen processing using dead cell vaccines. Adjuvants are substances incorporated into vaccine formulations to accelerate, enhance, or prolong the specific immune response. Mechanisms of adjuvant action can include increasing the half-life of vaccine antigens in vivo, inducing the production of immunomodulatory cytokines or other immunomodulatory molecules, or improving vaccine delivery to antigen-presenting cells (APC) and enhancing antigen processing or presentation (Vogel 2000). In a sense, live immunization has the potential to meet all of these needs although microorganisms that target APCs and modify their activity could be particularly attractive.

EXAMPLES OF VIRAL AND BACTERIAL VECTORS

Various attenuated vaccine strains have been modified to present heterologous antigens to the immune system. These combined vaccines can be based on attenuated strains, which in their own right can be used as vaccines against a particular disease, e.g. *Salmonella enterica* serovar Typhi (*S. typhi*) strains that have been developed as human oral typhoid vaccines and have been exploited as carriers with the aim of extending the range of protection (Tacket et al. 2000b). In contrast vaccinia viruses, which are the basis of smallpox vaccines, have been exploited with more focus on their simple use as

vectors, although the emphasis may change in the future now that smallpox vaccines are back on the agenda (Fauci 2002). Many different pathogens have been engineered as vectors for expression of polypeptides from other pathogens. A list of some of these is provided in Table 1 which is not comprehensive but includes some selected examples. The goal of the use of these vectors is to present foreign antigen to the immune system in the context of live vector and thereby develop broad immunity (humoral and cellular) to the corresponding pathogen from which the antigen is derived. The recombinant polypeptide is expressed and either transported to the host cell surface to stimulate antibody production or is broken down into peptides that are transported to the cell surface in the context of major histocompatibility complex (MHC) molecules, where they elicit cellular responses such as CTL responses. In other words, immunity to the heterologous antigen is enhanced through co-delivery with the vector. Clearly, the type of immunity induced will be greatly influenced by the choice of vector for delivery. Also, different antigens may be more suitable for delivery by one vector compared with another, e.g. many viral proteins cannot be easily expressed in a conformationally correct form in bacteria so viral vector delivery might be the best option in these cases. Alternately, *Salmonella* may be more attractive for delivery of an antigen from another enteric bacterium, particularly if mucosal targeting is desired. In this chapter, examples of representative vectored delivery systems are described but there is no attempt to cover all vectors.

Attenuated viral vectors

Attenuated viruses can be modified for use as vaccine carriers by inserting sequences encoding target antigens into their genome. A number of different viruses have been engineered as vectors for expression of 'foreign'

Table 1 *Examples of host/vector system*

Vector	Antigen	Reference
BCG	*Borrelia burgdorferi* OspA	Langermann et al. (1994a, 1994b)
	Toxoplasma gondii GRA1	Supply et al. (1999)
	Plasmodium yoelii (MSP-1)	Bruna-Romero et al. (2000)
	SIV Gag, Pol, Env, and Nef	Leung et al. (2000)
	Measles virus N protein	Zhu et al. (1997)
	Schistosoma mansoni Sm28GST	Kremer et al. (1996)
	HIV-1 V3	Kawahara et al. (2002)
	Schistosoma haematobium Sh28GST	Kremer et al. (1998)
	Pertussis toxin subunit S1	Abomoelak et al. (1999)
	Leishmania surface protease gp63	Connell et al. (1993)
Salmonella	*Helicobacter pylori* urease	Londono-Arcila et al. (2002)
	L1 papillomavirus	Revaz et al. (2001)
	Hepatitis B virus core	Schodel et al. (1996)
	Toxin hybrid	Barry et al. (1996)
	Plasmodium falciparum (NANP)	Ruiz-Perez et al. (2002)
	Pneumococcal PspA	Kang et al. (2002)
	Lassa virus nucleocapsid protein	Djavani et al. (2001)
	Tuberculosis ESAT-6	Mollenkopf et al. (2001)
	Leishmania mexicana gp63	Gonzalez et al. (1998)
	Pneumococcal surface protein A	Nayak et al. (1998)
Shigella	(HIV-1) gp120 DNA	Shata and Hone (2001)
	Measles virus DNA	Fennelly et al. (1999)
	HIV DNA	Vecino et al. (2002)
Yersinia	*Brucella abortus* P39 DNA	Al-Mariri et al. (2002)
Bordetella pertusis	*Schistosoma mansoni* Sm28GST	Mielcarek et al. (1998)
	Neiserria meningitidis TbpB	Coppens et al. (2001)
MVA/Vaccinia	SHIV-89.6P	Barouch et al. (2001)
	Herpes simplex virus-2 glycoprotein D	Meseda et al. (2002)
	Leishmania infantum P36/LACK	Gonzalo et al. (2001)
	Plasmodium yoelii (AdPyCS)	Bruna-Romero et al. (2000)
	Mycobacterium tuberculosis Ag85	Malin et al. (2000)
Adenovirus	*Mycobacterium tuberculosis* Mtb39	Lewinsohn et al. (2002)
	Foot-and-mouth disease virus	Grubman and Mason (2002)

polypeptides from other pathogens. The goal is to present foreign antigen to the immune system in the context of the live vector, so that the immune system responds to the antigen as a live immunogen and thereby develop broader immunity (humoral and cellular) to the corresponding pathogen. One advantage of this approach is that it is possible to avoid administering viruses such as HIV which could be considered unsafe even in an attenuated form. Recombinant vaccinia and related poxviruses have attracted particular attention as possible vectors for immunization against both infectious disease agents and cancers (Wang et al. 1995). Other viral vectors that have received considerable attention are the adenoviruses, which have also been used extensively for delivering genes as gene therapy vectors (Chen et al. 1996). The advantages of viral vectors include the production of the inevitable cellular damage that occurs during viral infection. Cellular damage could generate danger signals that could be a basis for activating the innate immune system. Viruses also have the potential to directly infect APCs with subsequent processing of viral antigens via the class I pathway.

However, there are obviously potential disadvantages with the use of viruses, particularly with the use of vaccinia vectors where the presence of pre-existing immunity can dampen responses to the heterologous antigen, compromising homologous boosting approaches. In addition, because of our limited repertoire of antiviral agents, there are additional risks from potential enhanced vaccine-associated infection in the immunocompromised.

The prototype viral vaccine vector is vaccinia virus, an animal-derived poxvirus that was used in the immunization program that successfully eradicated smallpox. Poxviruses are among the largest viruses and are almost visible to the naked eye using conventional microscopy. They harbor relatively large genomes and encode a variety of immunomodulatory proteins that can regulate the immune response during infection and potentially immunization. Different vaccinia derivatives harbor distinct repertoires of immunomodulatory genes and differ in their potential to replicate in different mammalian hosts. Hence, it is possible to have both replication-proficient and replication-defective forms of poxvirus vectors. Fowlpoxvirus and canarypox viruses are also being developed as live vectors that can infect human cells, but not produce infectious viral progeny (Moss 1992), thus providing a mechanism for natural attenuation (Fries et al. 1996). This clearly has implications for both immunogenicity and safety.

Many different recombinant polypeptides have been expressed in vaccinia virus, and immunization of animals with such vectors can protect against the pathogen encoding the recombinant polypeptide (Moss 1992; see Table 1). This approach has become routine as an experimental system. Some of the recombinant vaccinia viruses, e.g. those expressing influenza virus hemagglutinin and type I herpesvirus glycoprotein D have been shown to be protective in mice against subsequent challenge with the corresponding virulent heterologous viruses (Bennink et al. 1984). Recombinant vaccinia virus immunization has also now been extended to several veterinary target species. However, live recombinant vectors that can replicate in vivo may not be considered sufficiently safe for widespread use as prophylactic vaccines in humans.

To increase the safety of the poxviruses as vaccine vectors, the replication-incompetent strains have been exploited. Modified vaccinia virus Ankara (MVA) is replication impaired in primary human cells (Blanchard et al. 1998) and has been proposed as an alternate safe vaccine for use in smallpox eradication programs. The genome of MVA has also been sequenced and harbors six large deletions resulting in a loss of 31 kb of the genome. Lost genes include those encoding receptors for IFN-γ, tumor necrosis factor α (TNFα), type I IFN, and CC chemokines (Blanchard et al. 1998). Although delivery by MVA can be used to enhanced immunogenicity often this approach alone is not sufficient to induce protection. The potency of MVA/vaccinia immunization can be further enhanced by adopting 'prime-boost' strategies. A particularly fruitful approach has been to use an initial DNA vaccine as a priming agent followed by a recombinant viral vector such as modified vaccinia as a boost (Ramshaw and Ramsay 2000). The ability to induce $CD8^+$ CTL responses can be greatly increased by combining DNA vaccines with attenuated live viral vectors encoding the same or similar antigens (Sutter and Moss 1992; Ramshaw and Ramsay 2000). This prime-boost strategy has been further enhanced by co-administering cytokines such as IL-12, IFN-γ, or granulocyte–macrophage colony-stimulating factor (GM-CSF) (Chow et al. 1998). In the murine malaria model, immunization with DNA or MVA vaccines alone did not induce complete protection against virulent challenge, whereas a heterologous prime-boost strategy of DNA priming followed by MVA boosting was highly effective at inducing $CD8^+$ T cells and conferred complete protection (Schneider et al. 1998). Similar success in enhancing immunogenicity has been obtained with immunization exploiting viral antigens (Degano et al. 1999) and strongly reactive antigen-specific $CD8^+$ CTL responses have been demonstrated in primate models of HIV infection (Allen et al. 2000). Alternate prime-boost strategies, involving initial immunization with DNA or viruses and boosting with the relevant heterologous protein, have generally been poor inducers of CTLs, with specific humoral responses being stronger (Excler and Plotkin 1997).

Clinical trials using the MVA-based approach are under way for several infectious diseases including malaria (Seder and Hill 2000) and there is much interest in determining whether prime-boost methods can

enhance the cellular responses to tumor-associated antigens. Animal studies have already shown that heterologous boosting strategies can be useful in increasing the efficacy of recombinant DNA anti-cancer vaccines (Irvine et al. 1997) and early trials in humans appear promising (Bonnet et al. 2000; Oertli et al. 2002).

Many other viruses have been used as carriers of heterologous antigens in immunization experiments. One of the most spectacular projects has been the exploitation of the components of the yellow fever flavivirus genome as a platform for vaccines against several diseases including dengue (Guirakhoo et al. 2001). A yellow fever–dengue live chimeric vaccine has been taking into the clinic with excellent safety and immunogenicity profiles (Monath et al. 2002). This vaccine has the potential to be the first licensed recombinant viral carrier for humans. The use of some viruses such as polio virus as carriers is compromised to some extent by the relatively small capacity of the genomes to incorporate the genes for heterologous antigens but nevertheless some interesting progress has been made (Mandle et al. 2001). Adenoviruses have been extensively exploited as vectors for gene therapy and have also received attention as live vaccine components, particularly in prime-boost immunization (Gilbert et al. 2002). Adenoviruses have the potential to be used as mucosal targeting agents increasing their potential. Other viruses such as herpesviruses (Varghese and Rabkin 2002) have also been tested as experimental live carriers, resulting partly from their ability to infect nondividing cells, potential high expression levels and broad host-range.

Live attenuated bacteria as vaccine vectors

Various bacterial species have been studied for their ability to deliver heterologous antigens, including *Salmonella*, *Shigella* spp., *Escherichia coli*, and *Listeria* spp. (Shata et al. 2000). Bacteria as live vectors have the potential advantage over viruses in that their genomes are theoretically able to harbor many foreign genes, in contrast to viruses, which offer limited capacity to encapsulate foreign DNA. Recent advances in our understanding of the molecular pathogenesis of bacterial infections, particularly the roles of virulence genes and pathogenicity islands (Jones and Falkow 1996; Groisman and Ochman 1996) have encouraged the rational development of attenuated strains for use as vaccines (Levine et al. 1996). The ideal bacterial vaccine vector should retain enough infectivity to invade and target APCs, while eliciting an effective immune response with a minimum of reactogenicity (Raupach and Kaufmann 2001). The most common bacteria used as live vectors are members of the Enterobacteriaceae and the mycobacteria, particularly BCG. *Salmonella* Typhi has been the focus of the many efforts in terms of live vaccine development and clinical testing (Tacket et al. 2000a). *Shigella flexneri* has also been engineered to deliver different heterologous antigens. Interestingly, attenuated *S. flexneri* was used as a prototype strain to delivery antigens encoded on recombinant plasmids capable of driving antigen expression from eukaryotic promoters (as a combined live vector/nucleic acid vaccine) (Sizemore et al. 1995). *S. flexneri* are known to readily escape from intracellular vacuoles into the cell cytoplasm in vivo, possibly facilitating the transfer of DNA from the bacteria to the eukaryotic nucleus or transcription apparatus.

Salmonella as live vectors

Attenuated mutants of *S. enterica* have been extensively exploited for the delivery of heterologous antigens for immunization against bacteria, parasites, and viruses (Chatfield et al. 1989). Also, in recent years, these bacteria have been increasingly used in experimental models of anticancer immunization (Chabalgoity et al. 2002). In contrast to killed bacterial preparations, live attenuated *S. enterica* can induce cellular immune responses to bacterial and heterologous recombinant antigens (Hormaeche et al. 1995). *Salmonella* Typhi also offers the attraction of being deliverable via the mucosal route. After oral ingestion, attenuated *Salmonella* Typhi has the potential to invade or interact with Peyer's patch-associated M cells, enterocytes, macrophages, and DCs. Hence, the combination of mucosal delivery and immune targeting has encouraged research in this area.

Salmonella Typhi is a serovar of *S. enterica*. As *Salmonella* Typhi is human restricted much of the work associated with salmonella vaccine development has focused on *S. enterica* serovar Typhimurium (*Salmonella* Typhimurium) which is adapted to the mouse and consequently is much more convenient to study. By selecting the combination of attenuating mutations carefully, it is possible to design *S. enterica* derivatives with differing potential to replicate to some extent intracellularly or to disseminate to reticuloendothlial tissues in different hosts (Sirard et al. 1999). Thus, not only can the immunogenicity of the strain be modified, but the degree of dissemination in normal or immunocompromised individuals can theoretically be controlled. This has even been shown to be the case in humans where *Salmonella* Typhi *aro* mutants were able to disseminate, whereas similar *Salmonella* Typhi *aro*, *htrA* mutants were not detected in blood of human volunteers (Tacket et al. 1997). Many different attenuated derivatives of *S. enterica* have been constructed and characterized. Among the first defined mutant strains were the *aroA* auxotrophic derivatives of *Salmonella* Typhimurium which are defective in aromatic amino acid biosynthesis and dependent for growth on supplementation of aromatic compounds into their culture medium (Hoiseth and Stocker 1981). *Salmonella* Typhimurium *aroA* (and other single or

combination *aro* mutants) retain immunogenicity and favor stimulation of a Th1 response in mice (Dunstan et al. 1998). After oral administration to mice, these salmonella derivatives invade APCs in the gut mucosa and are retained within endocytic vacuoles (Figure 1).

The subsequent lack of their essential metabolic supplements induces many of the administered bacteria to die within 24–48 h, releasing their contents into the APCs. Compared with extracellular bacteria, antigens carried by *Salmonella* have the enhanced potential to be presented in association with MHC class I molecules by infected macrophages and DCs, clearly a desirable mechanism if protective $CD8^+$ T-cell responses are sought (Wick and Ljunggren 1999). However, it should be noted that repeated experiments have shown that *Salmonella* Typhimurium derivatives are less potent inducers of CTLs than many other adjuvants and delivery systems (Allsop et al. 1996). Nevertheless, the subsequent location of the recombinant antigens within the APCs may influence subsequent immunity. Interestingly some mutations, such as those in the *sifA* gene (Beuzon et al. 2000), increase the level of release of *Salmonella* Typhimurium from the vacuole in APCs and these mutations may have some potential for enhancing or modulating *Salmonella* Typhimurium-associated immune responses (Figure 1).

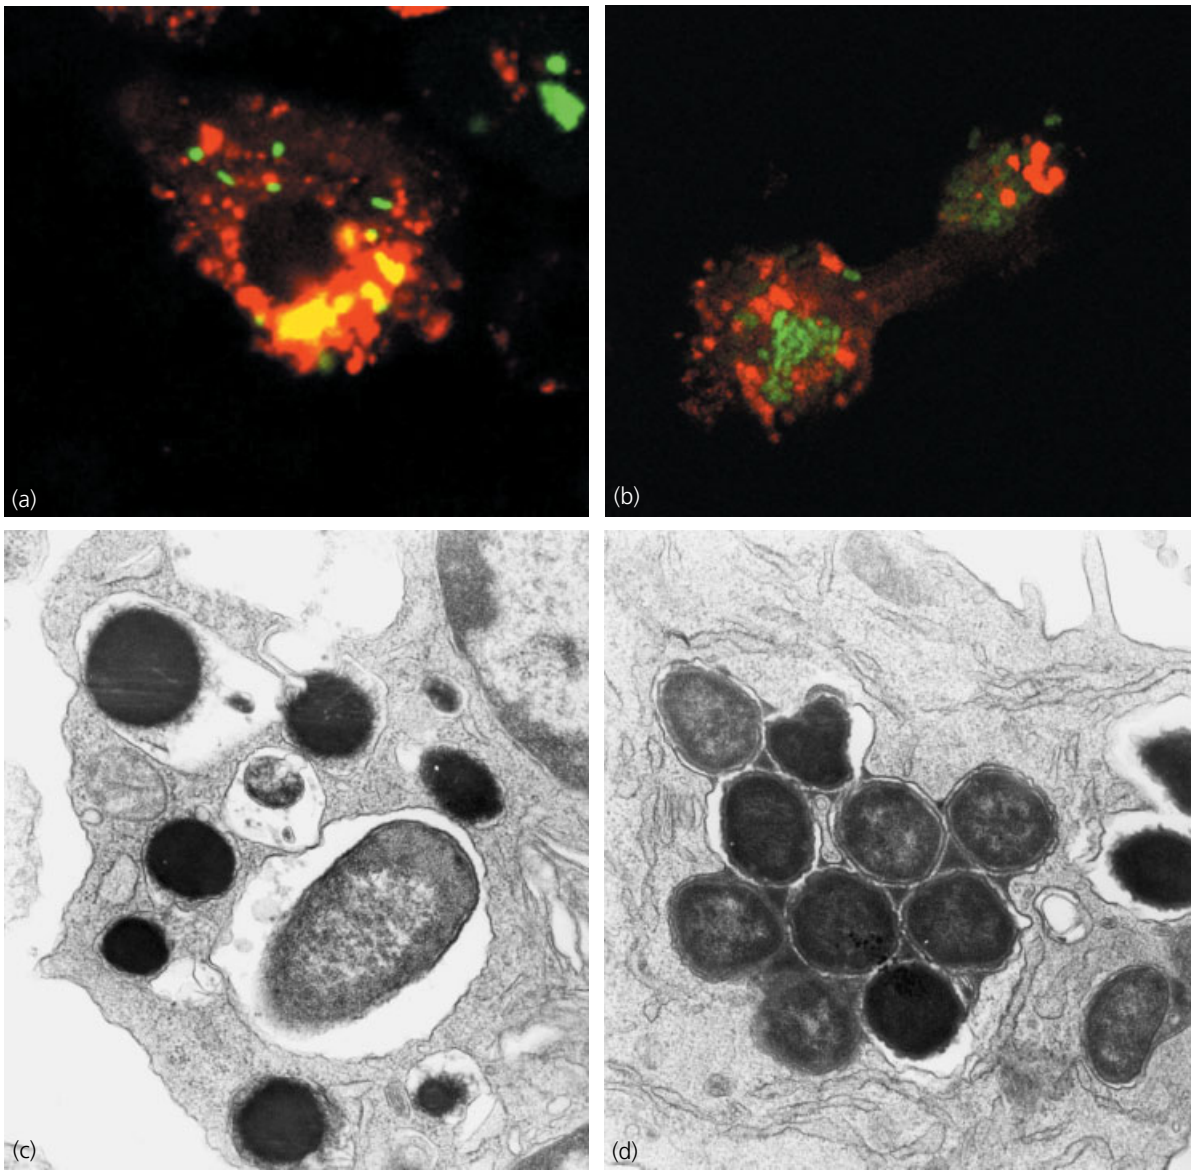

Figure 1 *Interaction of green fluorescent protein-positive* Salmonella *with dendritic cells cultured from the bone marrow of a mouse. Note that normal bacteria* **(a)** *interact with MHC molecules (yellow color) whereas sifA mutants* **(b)** *which escape the vacuole do so less well. The equivalent electron micrographs showing sifA mutants escaping the vacuole are shown in* **(c)** *(wild-type* Salmonella*) and* **(d)** *(sifA mutant* Salmonella*).*

The location or distribution of the expressed heterologous antigen within the *Salmonella* Typhimurium carrier cell may influence the subsequent immune response to the antigen. Although antigens expressed in the bacterial cytoplasm can be used to immunize and protect effectively, surface expression or secretion has the potential to enhance immunogenicity to some antigens (Strugnell et al. 1992). Antigen location within the bacterial cell may be critical for the induction of CTL responses which are often poor and efforts have been made to target antigen to or beyond the surface of the bacterial cell (Hess et al. 1996). The subsequent route for processing and presentation of MHC class I-associated salmonella antigens may also differ between APCs (Yrlid et al. 2000). Furthermore, because *Salmonella* Typhimurium invasion of macrophages can induce apoptosis (Monack et al. 1996), membrane 'blebs' containing bacterial antigens (and potentially plasmid DNA) may be taken up and processed by DCs via the MHC-I and -II pathways, resulting in activation of $CD4^+$ and $CD8^+$ T cells (Yrlid and Wick 2000).

The genes that encode heterologous antigens are often introduced into salmonella vaccine strains on plasmids. Plasmids that direct the expression of potentially toxic foreign proteins under the control of unregulated promoters can be rapidly lost from attenuated bacterial vector strains in vivo (Maskell et al. 1987). This gene loss can significantly reduce the level of the immune response to the heterologous antigen. To maintain stable antigen expression and thus enhance vaccine immunogenicity, growth-phase inducible promoters may be required (Dunstan et al. 1999; Marshall et al. 2000). Alternately, the stability of heterologous antigen expression may be enhanced by placing genes encoding heterologous antigens on the bacterial chromosome (Strugnell et al. 1990).

The intracellular life cycle of *Salmonella* also appears well suited to delivering expression plasmids as DNA vaccines. Indeed, many studies of bacterial to mammalian gene transfer have been carried out using *Salmonella* Typhimurium (Weiss and Chakraborty 2001). *Salmonella*-mediated mucosal DNA immunization was effectively demonstrated in mice using *Salmonella* Typhimurium to elicit the expression of ActA and listeriolysin from eukaryotic promoters, encoded on plasmids delivered to eukaryotic cells via these bacterial vectors. The development of protective CTL and antibody responses against the listeria-derived antigens was demonstrated after immunization with live *Salmonella*Typhimurium vectors (Darji et al. 1997). *Salmonella* Typhimurium was also successfully exploited as a vector to induce protection against a murine fibrosarcoma expressing β-galactosidase as a model tumor antigen using both eukaryotic and prokaryotic promoters to drive antigen expression (Paglia et al. 1998; Medina et al. 1999). Interestingly, in a mouse model of melanoma, attenuated *Salmonella* Typhimurium was used to deliver a DNA vaccine construct harboring the murine ubiquitin gene fused to minigenes encoding peptide epitopes gp100(25–33) and TRP-2(181–188). Immunized mice displayed protective anti-tumor immunity (Xiang et al. 2000). Similarly, transgenic mice expressing the tumor antigen carcinoembryonic antigen (CEA) had their peripheral tolerance broken by oral DNA immunization, with *Salmonella* Typhimurium, generating protection against CEA-expressing lung carcinoma cells (Niethammer et al. 2001).

Shigella

A great deal of effort has been made to generate different shigella derivatives for use as live oral vaccines against *Shigella*-associated dysentery. Despite many promising starts many candidate vaccines have floundered because of reactogenicity or poor immunogenicity in volunteers. Consequently, there are no licensed live shigella vaccines. *Shigella* has long been considered as a potential carrier of heterologous antigens. Early nonrecombinant experiments used hybrid genetic crosses between *Shigella* and the genomes of other enteric bacteria as possible extended-spectrum diarrhea vaccines. However, this approach ultimately proved unfruitful. As with *Salmonella*, *Shigella* spp. are also facultative intracellular bacteria but in comparison they have an enhanced ability to escape from the vacuole, become motile within the cytoplasm, and spread directly to adjacent cells (Sansonetti et al. 1986). A number of attenuated shigella mutants are available as experimental vaccines and these have been exploited (Karnell et al. 1995) to carry heterologous antigens (Noriega et al. 1996). An auxotrophic shigella mutant, dependent on supplementation with diaminopimelate (*dap*) for cell wall synthesis, was used for the first demonstration of functional DNA transfer from bacteria to mammalian cells (Sizemore et al. 1995). Since then, several studies have shown the induction of strong $CD8^+$ immune responses against viral antigens delivered as DNA vaccines by *Shigella* (Fennelly et al. 1999; Shata and Hone 2001). In a murine model of DNA immunization against HIV antigens, a *dap*-dependent shigella vector stimulated higher levels of IFN-γ-secreting $CD8^+$ cells compared with either *Salmonella* Typhimurium or *Salmonella* Typhi Ty21a (Vecino et al. 2002).

BCG

BCG is an attenuated live bacteria derived from a virulent *Mycobacterium bovis* by extensive laboratory propagation and is widely used for human and animal immunization. *Mycobacterium* spp. have the capacity to establish persistent infections and in vivo recombinant BCG may provide a continuous and prolonged stimulation of the cellular immune system. Both cellular and humoral immune responses against a number of foreign antigens delivered by BCG have been observed in mice and other species including primates such as the rhesus

monkey (Leung et al. 2000). Some of the BCG-based heterologous vaccines have been demonstrated to elicit protection against the corresponding pathogen. BCG expressing the outer surface protein A (OspA) from *Borrelia bugdorferi* induced a long-term protective response after intranasal immunization. Highly sustained levels of anti-OspA and BCG-specific secretory IgA and serum IgG responses were observed (Langermann et al. 1994a, b). As BCG vaccine can be given at birth, without interfering with maternal neutralizing antibodies, the possibility of administering recombinant antigens against childhood diseases such as measles has also been explored in rhesus monkeys. Intranasal administration of recombinant BCG producing the measles virus N nucleoprotein provided protection against subsequent challenge with measles virus. Even though immunization did not prevent systemic infection, immunized monkeys showed a significant reduction of lung inflammation and reduced virus titers in lymph nodes. Nucleoprotein specific T-cell proliferative responses to the measles virus were detected in the absence of anti-N antibody response, suggesting T-cell prevention of virus-induced lung pathology (Zhu et al. 1997). Recombinant BCG vectors can induce humoral and cellular immune response to the major proteins of simian immunodeficiency virus (SIV) polypeptides Gag, Pol, Env, and Nef in rhesus monkeys. A single simultaneous inoculation of all four recombinants elicited SIV-specific IgA and IgG antibodies, as well as cellular immune responses, including CTL and helper T-cell proliferation (Leung et al. 2000). Live BCG secreting a carboxyl terminus of MSP-1 from *Plasmodium yoelii* induced more efficient protective immunity against plasmodium challenge, inducing MSP-1-specific antibodies and IFN-γ (Bruna-Romero et al. 2000).

Other bacterial vectors

Vaccines based on *Escherichia coli* vectors are at a relatively early stage of development. Investigators have concentrated on trying to maximize the targeting of antigens to macrophages and DCs. One approach has been to link heterologous protein expression to the α-haemolysin (HlyA) type I secretory system of uropathogenic *E. coli* to release antigens into the phagosome or cytosol of infected cells (Gentschev et al. 2002). An alternate method of increasing cytosolic antigen delivery (and therefore MHC-I presentation of antigen) is to enable *E. coli* itself to escape from the phagosome. This was demonstrated by transforming an attenuated auxotrophic *E. coli* mutant with a plasmid encoding the *hly* gene from *Listeria monocytogenes*, thereby producing the pore-forming listeriolysin and releasing bacteria and their carried antigens into the cytosol (Higgins et al. 1999). One potential problem with the use of *E. coli* for delivery is that these bacteria normally reside in the lumen of the intestine and consequently may be inherently less immunogenic than the invasive enteric bacteria. DNA delivery using modified *E. coli* strains has been achieved by adapting *E. coli* to express the *invasin* gene from *Yersinia pseudotuberculosis* to enhance the invasion rate of nonphagocytic cells and enhance vacuole escape through the hemolysin (Grillot-Courvalin et al. 1998). The bacterium *L. monocytogenes* can also efficiently escape from intracellular vacuoles, replicate in the cytosol, and spread directly to adjacent cells, albeit at a lower efficiency than *Shigella* (Tilney and Portnoy 1989; Chastellier and Berche 1994). *Listeria* has a powerful ability to stimulate MHC-I-restricted $CD8^+$ cytotoxic immunity to itself and, potentially, carried antigens (Schafer et al. 1992). A number of attenuated listeria mutants have been adapted for heterologous antigen delivery (Dietrich et al. 1998; Thompson et al. 1998). An attenuated listeria mutant was used to induce immune responses against influenza nucleoprotein serving as a model antigen in tumor cells, and protection was induced against challenge with tumor cells expressing this antigen (Pan et al. 1995). The anti-tumor response involved the stimulation of multiple effector pathways, including $CD4^+$ and $CD8^+$ T cells, DCs, NK cells, and several key cytokines including IL-2, IL-4, IL-12, IFN-γ, and TNF-α (Weiskirch et al. 2001). Attenuated listeria mutants have also been used in several other murine tumor models including immunization against a β-galactosidase-expressing fibrosarcoma (Paglia et al. 1997), E7 protein from the cervical cancer-associated human papillomavirus 16 (HPV16), and a lymphocytic choriomeningitis virus (LCMV) nucleoprotein-expressing glioma (Liau et al. 2002).

ENHANCED TARGETING OF THE IMMUNE SYSTEM WITH LIVE VECTORS

The mechanisms by which the immune system protects against disease are diverse and include the induction of neutralizing antibodies and the generation of T-cell responses, including T-helper cells and CTLs. Antibodies provide protection against some bacteria by recruiting bactericidal mechanisms and neutralizing bacterial toxins. Antibodies also play a pivotal role in protection against some viral diseases, such as polio, by virus neutralization mechanisms and preventing viruses from infecting cells. T cells contribute to resistance to bacterial and viral diseases by producing cytokines and inflammatory molecules, which can stimulate antibody, macrophage activation, and CTL responses. Several strategies have been developed specifically to enhance CTL immune responses and improve antigen presentation on MHC-I molecules. Viral and bacterial vectors that can actively invade cytoplasm of host cells have been introduced into APCs for targeted delivery to the immune system. Live vectors that have been used for this purpose include vaccinia, canarypox virus, adenoviruses, *L. monocytogenes*, *Salmonella*, and BCG.

Based on their biology and ability to present antigens, DCs have been described as 'nature's adjuvant' (Banchereau and Steinman 1998) and this is one of the key reasons why some recent therapeutic strategies have incorporated DCs as an effective way to target carrier vectors to immune sites (Banchereau et al. 2001). While in an immature, sentinel state, DCs effectively take up antigens, and subsequently process them through both the class I and II MHC pathways, a step required for the efficient activation of $CD8^+$ CTL and $CD4^+$ T-helper cells. After exposure to certain infectious agents, inflammatory cytokines, or activation of their CD40 receptors, DCs are mobilized from the site of antigen uptake to the peripheral lymphoid organs, where encounter with antigen-specific T cells can take place. During this migration, DCs mature into cells that are specialized in presenting high numbers of peptide/MHC complexes in a rich co-stimulatory context (Banchereau et al. 2000), necessary for activating T-cell responses. The level of maturation of the DCs may be of critical importance in the nature of immune response to DC-delivered antigen. Recent studies suggested that, in some cases, antigen-loaded mature DCs induce a protective (Th1) immune response, whereas antigen-loaded immature DCs may 'silence' the immune response via expansion of IL-10 producing T cells (Jonuleit et al. 2000; Dhodapkar et al. 2001). The expression pattern of different chemokines and chemokine receptors involved in homing dendritic cells to the lymphoid organs also varies throughout the dendritic cell maturation process (Sallusto et al. 1999). DCs have also been shown efficiently to take up and crosspresent antigens from apoptotic or necrotic cells in their vicinity (Albert et al. 1998). This hallmark has being used as a means to target antigens directly to DCs in vivo. Fas-mediated apoptotic cell death can lead to more efficient delivery of HIV-1 antigens to professional APCs, enhancing the priming of antigen-specific CTLs (Chattergoon et al. 2000).

As DCs are critical for the initiation of a cellular immune response, they have become a focus for many researchers to examine the possibility of inducing protective immunity against intracellular pathogens. DCs can efficiently internalize and process live intact bacteria for presentation by both MHC-I and -II molecules (Yrlid and Wick 2000). The bacterial carriers may function as a natural adjuvant, because they can induce the release of proinflammatory mediators such as TNFα, IFN-γ, and IL-12 and enhance early innate immunity, which creates an inflammatory context that probably induces dendritic maturation and antigen-presenting function (Banchereau and Steinman 1998). Bone marrow-derived DCs pulsed ex vivo with BCG and administered intratracheally can generate activated T cells and IFN-γ-secreting cells in the draining lymph nodes, leading to significant protection against aerosol *M. tuberculosis* infection (Demangel et al. 1999) in mice. Likewise, DCs pulsed ex vivo with killed *Chlamydia* and administered intravenously to mice-primed $CD4^+$ T cells provided protection against genital chlamydial infection equivalent to that obtained after immunization with live organisms. Besides intracellular pathogens, DCs have been successfully used as a vaccine against noninvasive, extracellular bacteria. DCs pulsed ex vivo with *Pseudomonas aeruginosa* and administered intravenously to mice induced a $CD4^+$ T-cell proliferative response and prolonged survival after a lethal pulmonary challenge with *P. aeruginosa* (Worgall et al. 2001). Homologous or even heterologous DCs pulsed with heat-killed *Bordetella pertussis* administered intravenously or intranasally to mice induced protective immune responses associated with strong *B. pertussis*-specific IgG and IgA responses in the lung (George-Chandy et al. 2001).

Monocyte-derived DCs infected with live viral replicative or nonreplicative vectors are being used as an effective means of delivery in HIV-1 vaccine development. Nonreplicative viruses are considered as a safer approach for immunizing human volunteers, but are typically weak immunogens, leading to efforts to target the vaccine to DCs for eliciting effective antivaccine immunity such as expanded CTL production. Immature monocytic DCs infected with vesicular stomatitis virus–pseudotyped HIV-1 presented antigens to $CD4^+$ and $CD8^+$ T cells from HIV-infected individuals as effectively as replicative pox vectors (Granelli-Piperno et al. 2000). Replicative recombinant canarypox (ALVAC) HIV-1 vaccines have been administered to >200 HIV-seronegative individuals with a good safety profile. However, this vaccine elicited antigen-specific CTLs in only a third of the volunteers, and therefore, in an attempt to engineer a better vaccine, monocytic DCs pulsed ex vivo with the vaccine are being considered as a possible delivery route for targeting immune cells. Preclinical data showing that the infected DCs are functional in T-cell stimulation assays performed using cells from HIV-1-infected individuals support the ongoing HIV vaccine trial that is comparing conventional vaccine delivery routes with ex vivo vaccine-loaded autologous DCs.

Adenoviruses are ubiquitous human pathogens and can be used efficiently to transduce a wide range of human cells and tissues, including DCs. With this property in mind, adenoviruses have been considered as a vaccine delivery vector, but a recent report by Roth et al. (2002) suggested that pre-existing antiviral immunity may limit the possibility of their clinical application.

INFLUENCE OF ROUTE OF DELIVERY

The route of delivery of a vaccine can have a major influence on the type of immunity induced. The mucosal route has been an attractive option for avoiding the use of needles and stimulating local mucosal immunity along with systemic responses. The oral route of vaccine administration is particularly attractive, but the ability to elicit mucosal immunity using nonliving antigens

involves the use of high doses of antigens and repeated administrations. This results partly from the instability of the antigens in the proteolytic and acidic environment of the stomach, but is also caused by the poor natural mucosal immunogenicity of many antigens at mucosal surfaces. Clearly, live delivery offers potential advantages for oral immunization. However, there are still potential problems. There is potential strong ecological competition for live vectors with resident commensal flora in the gastrointestinal tract. Already problems have been encountered in moving some live vaccines from western volunteers into the field in less developed countries and the normal flora, together with immunological barriers, may be responsible. However, such barriers may not exist for all vaccine vectors.

An attractive alternative to oral delivery is potentially the intranasal route of immunization. Intranasal immunization has the advantage that the respiratory tract is less acidic and also less heavily colonized by microorganisms than the gastrointestinal tract. Less antigen is also needed to induce mucosal immunity via the intranasal compared with the oral route (Douce et al. 1999). Several vectors, including BCG and *Salmonella* Typhi, have been successfully used to deliver heterologous antigens via both the oral and intranasal routes (Langermann et al. 1994a; Hopkins et al. 1995; Corthesy-Theulaz et al. 1998; Kremer et al. 1998). Specific antigen presentation by the resident APCs in the respiratory and gastrointestinal tracts can differ compared with the systemic immune response. When recombinant BCG expressing an intracellular 28-kDa glutathione *S*-transferase from *Schistostoma haematobium* (Sh28GST) was administered intranasally to mice, the vaccine induced high levels of humoral systemic immune responses to Sh28GST, levels similar to responses after intraperitoneal administration of the recombinant antigen. Intranasal delivery also induced a mucosal IgA response against Sh28GST, which was not elicited after intraperitoneal administration. This anti-Sh28GST response was greatly enhanced after a second intranasal immunization that remained high for at least 12 weeks after the boost (Langermann et al. 1994b). When the related 28-kDa glutathione *S*-transferase from *Schistostoma mansoni* (Sm28GST) was administered intraperitoneally, this antigen also induced equivalent levels of anti-glutathione *S*-transferase (anti-GST) antibodies, but, surprisingly, intranasal administration of Sm28GST induced lower levels of anti-GST antibodies than Sh28GST (Kremer et al. 1996).

As transmission of HIV occurs predominantly via mucosal surfaces, immunization targeted to the induction of HIV-specific immune responses at mucosal sites could contain viral replication in the early stages of infection. Many studies have investigated the effect of the route of immunization with recombinant modified vaccinia viruses on eliciting mucosal immune responses. Mucosal immunization of macaques, with MVA-based vectors expressing the simian–human immunodeficiency virus (SHIV) strain SHIV89.6gp160, provided better protection than subcutaneous immunization, after intrarectal exposure to SHIV. These studies suggest that cutaneous or intramuscular immunization generated antigen-specific cells that may not travel to mucosal sites (Kantele et al. 1999; Cromwell et al. 2000). When highly attenuated poxvirus vectors (NYVAC) encoding the SIV_{makow} Gag, Pol, and Env products were introduced intramuscularly into macaques, they provided long-term virus containment after both intravenous or intracellular challenge with SIV_{mac251} (Benson et al. 1998). The results suggested that, even in the absence of priming at mucosal sites, systemic immunization can lead to virus control after mucosal challenge (Benson et al. 1998; Hel et al. 2001). However, a recent study, designed to explore the extent of the mucosal immune responses to a Gag-immunodominant SIV_{mac251} epitope after intramuscular, intranasal, or intracellular route of immunization with highly attenuated poxvirus NYVAC/SIV_{gpe} in macaques, concluded that immunization with live vector vaccine results in the elicitation of $CD8^+$ T-cell responses at mucosal sites even when the vaccine is delivered by nonmucosal routes (Stevceva et al. 2002).

CONCLUSIONS

Live vectors are receiving considerable attention as vehicles for the efficient delivery of antigens via several different routes of immunization and in a number of different target species including humans. In humans, some vectored delivery systems have proved to be less immunogenic than in model animals, e.g. *Salmonella* Typhimurium vectors in mice have consistently proved more efficient at heterologous antigen delivery compared with *Salmonella* Typhi in humans. This could be the result of inherent differences in the immunogenicity of *Salmonella* Typhimurium compared with *Salmonella* Typhi vectors (Hindle et al. 2002) but is equally likely to be the result of the use of poorly optimized expression systems used to drive the expression of the heterologous antigens in the clinical studies. The application of optimized delivery systems together with prime-boost approaches may prove fruitful for the development of a new generation of live human vaccines.

Augmenting the immunogenicity of DNA vaccines	8	References	13

Over the last decade, there has been considerable excitement about the potential of a radically new approach to infectious disease prophylaxis stemming from the development of 'naked' DNA vaccine technology. Although previous vaccine strategies have relied on using a live replicating vector, purified protein, or an attenuated version of the pathogen, DNA vaccines consist of a plasmid DNA expression vector encoding the gene of interest for targeting the immune response. When administered to an animal, cellular uptake of the plasmid DNA results in expression of the encoded antigen in situ, leading to the induction of antigen-specific immunity.

In many ways, DNA vaccines share attributes of live attenuated vaccines, as exemplified by their ability to synthesize native protein for B-cell recognition and generate antigens endogenously, to enter the major histocompatibility complex (MHC) class I processing pathway and stimulate induction of $CD8^+$ cytotoxic T lymphocytes (CTL). However, unlike live vaccine vectors, DNA vaccines are noninfectious (therefore considered safe to administer in immunocompromised individuals), relatively easy to engineer and manufacture, and heat stable, and can easily be lyophilized (therefore without the need for cold storage). Despite the elegance and simplicity of DNA vaccines, the generation of a strong humoral immune response has not been as universally successful as immunization with protein combined with an adjuvant. This may be the result of the small amount of antigen that is produced. Studies with plasmids encoding reporter proteins indicate that only picogram to nanogram amounts of protein are expressed (Wolff et al. 1990; Klavinskis et al. 1999).

This chapter discusses the background to this technology, the architecture of the vectors used for immunization, modes of administration, the immunological basis for the responses elicited by DNA vaccines, current approaches to augment vaccine potency, and considers safety for human use, including findings from early human clinical trials.

HISTORICAL BACKGROUND

The inception of DNA vaccines goes back to a largely unnoticed observation by Ito (1960) who demonstrated the induction of papillomas in rabbit skin by injection of purified nucleic acid extracted from the Shope rabbit papilloma virus. It was not until Wolff et al. (1990) reported that intramuscular injection of plasmid DNA in a simple saline solution could transfect muscle cells in vivo and persist in an episomal form that the potential to induce an immune response against the expressed proteins became appreciated. Tang et al. (1992) were the first to demonstrate induction of antigen-specific antibody from plasmid DNA injected via a 'gene gun' into mice. This was rapidly followed by a consortium from Vical and Merck (Ulmer et al. 1993) who demonstrated that DNA vaccines could protect mice from influenza virus challenge by induction of

antibody and $CD8^+$ CTL responses. Since then, the immunogenicity or protective efficacy of DNA vaccines in preclinical models of infectious disease, allergy, and cancer has been established in several animal species, and attests to the simplicity and robustness of the technology.

DESCRIPTION OF DNA EXPRESSION VECTORS

DNA vaccines include the basic elements of a bacterial plasmid (the vector: Figure 1): a promoter and enhancer (to enable transcription of the inserted foreign gene), an mRNA transcription termination/polyadenylation signal (for directing expression in mammalian cells), an antibiotic resistance gene (to confer an antibiotic selectable marker for growth in *Escherichia coli*), an origin of replication for growth in *E. coli*, and specific nucleotide sequences, cytidine phosphate–guanosine (referred to as CpG motifs) that are stimulatory for lymphocytes and act as an adjuvant.

Plasmid vector

The essential feature of a plasmid DNA vector for optimal expression in mammalian cells is a strong promoter/enhancer and transcriptional/termination sequence. Most DNA vaccines contain the human cytomegalovirus (CMV) immediate/early (IE) promoter (Boshart et al. 1985), the SV40 early promoter (Moreau et al. 1981), or the Rous sarcoma virus long terminal repeat (LTR) (Gorman et al. 1982) in conjunction with polyadenylation sequences from bovine growth hormone (BGH) or SV40 to stabilize the mRNA (Pfarr et al. 1986). There is some evidence that interferon-γ (IFN-γ), released in situ during the priming of an immune response (as a result of the inflammatory cytokine-inducing properties of bacterial DNA), can suppress transcription from many viral promoters (Harms and Splinter 1995; Romero and Lavine 1996). This in turn can affect the magnitude of the immune response, by limiting antigen production for B- and T-cell priming. Alternatives to virus-derived control elements, based on promoter/enhancer sequences driving expression of MHC class I and II (Xiang et al. 1997; Gebhard et al. 2000), dectin (in Langerhans' cells: Bonkobara et al. 2001) and muscle-specific genes (Barnhart et al. 1998; Kwissa et al. 2000), have been used successfully in DNA vaccines. Tissue and/or cell-specific expression has been achieved by these promoter elements but levels of expression do not exceed those achieved from the human cytomegalovirus (HCMV) immediate early gene (IE) promoter combined with the CMV intron A. Further optimization of expression has been reported by the inclusion of a 'Kozak' translational initiation sequence 5′ to the start codon of the inserted 'foreign' gene.

The ColE1 origin of replication (ori) derived from bacterial pUC plasmids is generally included in DNA vaccine vectors, because it provides an increased copy number in bacteria and high yields of plasmid DNA on purification. Early DNA vaccines studied in mice contained the ampicillin resistance gene (for plasmid selection during bacterial culture); however, this is precluded for use in humans and has been replaced by

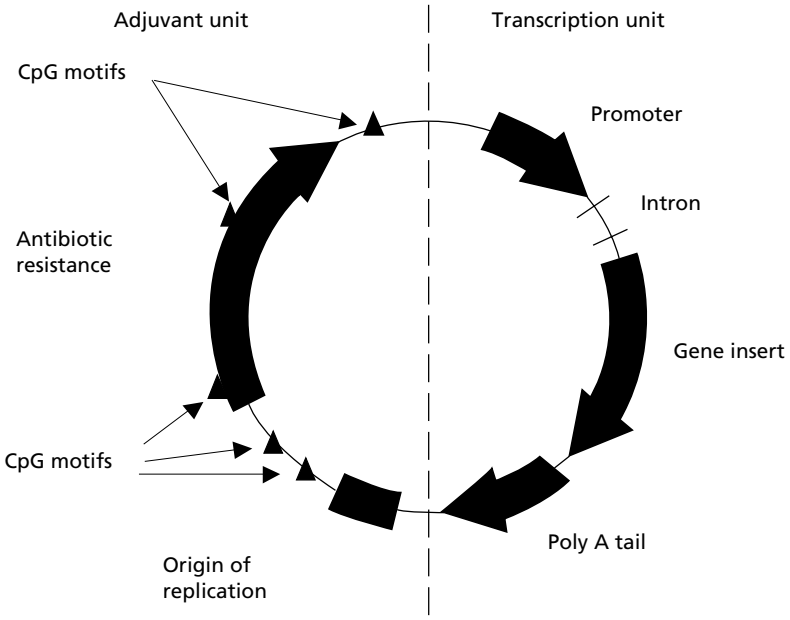

Figure 1 *Schematic representation of the basic elements of a plasmid DNA vector. The transcriptional unit consists of a viral promoter (e.g. human cytomegalovirus immediate early promoter), the gene of interest for targeting the immune response and transcription/termination sequences (poly-A tail). The backbone of the vector contains a bacterial origin of replication and an antibiotic resistance gene, which allow for growth and selection in bacteria. These elements of the vector also contain a number of CpG motifs and represent the adjuvant unit of the vector.*

kanamcyin or antibiotic-free approaches for selection of plasmid DNA (Cranenburgh et al. 2001).

CpG motifs of plasmid DNA

Aside from the regulatory elements of the vector concerned with transcription, bacterial plasmid DNA also contains immunostimulatory sequences (ISS) consisting of CpG dinucleotide sequences, usually flanked by two 5′ purines and two 3′ pyrimidines (Sato et al. 1996). Stimulatory bacterial CpGs differ from vertebrate DNA in that they are unmethylated and expressed at the expected frequency (predicted from random base utilization), whereas this frequency is suppressed 20-fold in vertebrate genomes (Bird 1986). These structural differences within bacterial DNA are recognized as 'foreign' by vertebrate immune systems and directly activate the innate immune system to produce multiple proinflammatory cytokines (including tumor necrosis factor α (TNF-α), IL-6, IL-12, IL-18, and IFN-α and -γ (Klinman et al. 1996)) which enhance the ability of antigen-presenting cells (APC) to present antigen and stimulate T-cell activation. This property of bacterial DNA has been described as the 'natural' adjuvant of DNA vaccines. Direct proof of the contribution of CpG DNA to the immunogenicity of DNA vaccines was provided by substitution of a CpG-containing ampR gene for a kanR-selectable marker (containing additional CpG motifs). The modified plasmid DNA was found to induce an enhanced CTL and IgG response compared with the original vector (Sato et al. 1996). This ability of CpG sequences in DNA vaccines to stimulate an immune response is abrogated by in vitro methylation (Pasquini et al. 1999). Co-administration of an empty vector (i.e. without any antigen-coding sequence) may boost the immune response to a DNA vaccine; however, there appears to be an upper limit to the ability of additional CpG motifs to improve the immune response (Krieg et al. 1998). This may reflect saturation of the innate cell-signaling pathway (see discussion below).

IMMUNOSTIMULATORY EFFECTS AND MECHANISMS OF CpG

Recognition of bacterial CpG is mediated by a conserved receptor, Toll-like receptor 9 (TLR9) expressed by macrophages and dendritic cells (DC) (Bauer et al. 2001). Current data suggest that CpG oligonucleotides cross the cell membrane via sequence nonspecific receptor-mediated endocytosis and are recruited to an endosomal compartment where TLR9 co-localizes (Ahmad-Nejad et al. 2002). One possibility is that plasmid-derived CpG oligonucleotides are liberated after degradation of injected plasmid DNA by extracellular nucleases. It appears that endosomal acidification of CpG DNA is required to initiate signaling via the Toll/interleukin 1 receptor (IL-1R) pathway, because specific inhibitors such as chloroquine block the immunostimulatory activity of CpG DNA (Hacker et al. 1998). In macrophages and DCs, CpG-DNA-mediated TLR9 signaling is transduced by a common adapter protein, myeloid differentiation factor 88 (MyD88), which results in the downstream generation of intracellular reactive oxygen species (Yi et al. 1998), and activation of the mitogen-activated kinases (MAPK) and nuclear factor κB (NFκB: Yi and Krieg 1998; Yi et al. 1998). The biological outcome of CpG-driven TLR9 ligation in DCs is secretion of T-helper 1 (Th1) polarizing cytokines (IL-12 and IL-18), upregulation of co-stimulatory molecules (CD40, CD80, and CD86) and functional maturation for antigen presentation (Sparwasser et al. 1998). These observations indicate that the plasmid backbone functions as a Th1-polarizing adjuvant in DNA vaccines and explains the IgG2a antibody and CTL responses seen after intramuscular immunization. CpG DNA also delivers T-independent survival signals to DCs, which are mediated by upregulation of the cellular inhibitor of active caspase (cIAP: Park et al. 2002). This might be a mechanism by which CpG DNA may prolong DC presentation of naked DNA-encoded antigen and compensate for the relatively low levels of antigen produced (compared with replicating vectors). CpG DNA also directly activates monocytes and macrophages to secrete Th1-like cytokines and express increased levels of cell surface co-stimulatory molecules (Schattenberg et al. 2000b). The signaling pathways activated by CpG DNA in B cells stimulate secretion of IL-6, IL-10, and IL-12 and also immunoglobulin in a polyclonal T-independent manner (Krieg et al. 1995). These CpG-mediated effects synergize with signaling through the B-cell antigen receptor by antigen secreted in situ from naked DNA.

Immune recognition of CpG DNA varies between species, with mouse cells expressing a high-responder phenotype and human cells a low-responder phenotype (Bauer et al. 2001). The CpG motifs optimally active in mice are poor stimulators of innate immunity in human peripheral blood mononuclear cells (PBMC: Bauer et al. 2001). Extensive screening assays have identified structurally distinct CpG oligodeoxynucleotide (ODN) sequences, with enhanced stimulation for human cells. K-type CpG ODNs stimulate IL-6 production by monocytes/DCs and B-cell proliferation and IgM production, whereas D-type CpG ODNs preferentially stimulate IFN-γ production by natural killer (NK) cells (Verthelyi et al. 2001). Thus, it may be possible to improve DNA vaccines for human use by the mutagenesis of endogenous plasmid CpG sequences. However, as discussed above, a relative increase in the levels of IFN-γ induced by CpG-DNA will be compensated by IFN-γ-mediated suppression of viral promoter activity, which drives antigen expression. A further level of complexity that is being unraveled is the differential responsiveness of human DC subsets. Human plasmacytoid DCs ($CD11c^-$ $CD123^+$) are responsive to CpG DNA, but monocyte-derived $CD11^+$ DCs lack TLR9 and do not appear to be

stimulated (Bauer et al. 2001). Currently, this difference is difficult to rationalize, in view of the front-line defensive location of $CD11c^+$ DCs at body surfaces.

IMMUNOSUPPRESSIVE CpG Motifs

Certain CpG motifs can be inhibitory and abrogate immune activation and cytokine production (Hacker et al. 1998). These motifs termed 'neutralizing' CpG (CpG-N) contain a dinucleotide motif preceded by a cytidine (i.e. CCG) followed by a guanosine (i.e. CGG) or contain CG repeats (CGCGCG). The immunostimulatory (s) activity of a CpG-S oligonucleotide can be blocked by certain suppressive motifs. Removal of the suppressive motifs from the plasmid DNA backbone improved the immunogenicity of the plasmid DNA (Krieg et al. 1998). These observations suggest that the presence or absence of these inhibitory sequences in DNA vaccines may profoundly affect the immunogenicity of the vaccine.

ROUTES AND MODE OF DNA VACCINE DELIVERY

A variety of routes have been used to deliver DNA vaccines. Systemic routes of delivery include intramuscular or intradermal needle injection, transdermal application via occluded patches, or ballistic delivery into the skin. For needle injection, naked plasmid DNA is administered in water, saline, phosphate-buffered saline, or sucrose solution. Ballistic delivery of DNA vaccines involves bombardment of cells with plasmid DNA precipitated onto gold or tungsten microparticles. This is usually achieved by a blast of pressurized gas (generally helium) delivering DNA-coated particles from a gene gun (Feltquate et al. 1997). Topical or aerosol delivery of naked DNA vaccines to mucosal surfaces has also been achieved and is highly desirable, because this provides the possibility of generating immunity both at the sites of pathogen entry and in the systemic compartment. Moreover, needle-free delivery increases patient compliance.

Intramuscular delivery of naked DNA

One of the simplest modes of administering naked DNA is in saline to the quadriceps or tibialis anterior muscle in mice or to the axillary or gluteal muscle in nonhuman primates. Typically 10–50 μg plasmid DNA is required to elicit a response in mice but substantially higher doses (1–5 mg) are required to elicit detectable responses in nonhuman and human primates. Some investigators have reported improved immune responses induced by pretreatment of the muscle tissue with agents including cardiotoxin, local anesthetics such as bupivacaine, or hypertonic solutions (Davis et al. 1993; Coney et al. 1994). Whether or not this effect reflects an increase in plasmid-encoded antigen expression in regenerating muscle cells or an increase in recruitment of APCs to the site of tissue damage is contentious. There is agreement that, after intramuscular injection, plasmid DNA rapidly disseminates throughout the body and persists briefly in highly vascular tissues and in muscle at the site of injection for at least 8 weeks (Parker et al. 1999). The persistence of plasmid DNA, principally in muscle cells, may provide a reservoir of antigen production to sustain (via crosspriming, see 'Processing and presentation of plasmid DNA-encoded antigen' below) the strong CTL responses reported in mice.

The characteristics and quantity of an antigen are known to be important in defining the type of immune response elicited. However, intramuscularly injected DNA vaccines typically, but not exclusively, elicit a Th1 immune response, characterized by IFN-γ production by antigen-restimulated $CD4^+$ T cells, and the predominance of serum IgG2a antibody to the antigen. This profile is attributed to the adjuvant effect of the CpG motifs within the plasmid backbone, which induce IL-12 secretion by APCs.

Intradermal or ballistic delivery of naked DNA

Intradermal or ballistically delivered DNA vaccines target the dermal and epidermal tissues of the skin. Small amounts of DNA, typically 1–10 μg (for needle injection) or sub-microgram amounts (for ballistic delivery), are required to elicit immune responses in mice that are often superior to those elicited at higher concentrations by the intramuscular route. This most probably reflects the higher concentration of APCs, Langerhans' cells, and dermal DCs within the skin and also the cascade of cytokines (IL-1α, IL-1β, TNFα, IL-6, IL-7, IL-10, IL-12, IL-15) and chemokines (macrophage inflammatory protein 1α (MIP-1α), monocyte chemoattractant protein 2 (MCP-2), RANTES, IP-10) that are liberated after needle or ballistic trauma. Initial reports suggested that gene-gun- (or ballistically-) delivered DNA vaccines elicited a predominantly Th2 response and serum IgG1 antibody, whereas intramuscular injection with the same plasmid DNA resulted in Th1 priming for CTLs and predominantly serum IgG2a antibody (Feltquate et al. 1997). Other reports indicate induction of potent Th1 responses after intradermal injection of plasmid DNA (Raz et al. 1994). These differences may be reconciled with the type of plasmid DNA-encoded antigen, the age and type of mouse strain used, and the dose of plasmid DNA (low doses contributing to exclusive Th2 priming), rather than a correlation between injection route and polarization of the immune response. It has been suggested that the adjuvant effect of plasmid DNA operates in priming Th1 responses at a dose range of 20–100 μg/vaccine (Reimann and Schirmbeck 2000), accounting for the preferential priming of Th2 responses by the intradermal or ballistic route. However, priming for Th1 responses

can be established at low plasmid DNA doses by co-injection of low concentrations of CpG oligonucleotide at the intradermal site of plasmid DNA delivery (Reimann and Schirmbeck 2000). Other reagents (IFNs, IL-12, IL-18, or poly[I/C]) can also deviate a plasmid DNA-elicited Th2 response to a Th1 type in this system.

Mucosal delivery

Protection against infection at the mucosal epithelia generally requires induction of local immunity, which is optimally elicited by vaccines delivered to mucosal inductive sites (Czerkinsky et al. 1999). To date, the vast majority of DNA vaccines have been delivered by parenteral routes, although data indicating induction of secretory IgA or IgG antibodies by intramuscularly or intradermally administered plasmid DNA have not been compelling (Fynan et al. 1993). A number of studies have reported the induction of weak immune responses by direct topical delivery of naked plasmid DNA to various mucosal surfaces, including the nasal, oral, and vaginal epithelia (Etchart et al. 1997; Wang et al. 1997; Klavinskis et al. 1999). These observations may be the result of the low efficiency of transgene expression achieved at nasal and intestinal epithelia by naked plasmid DNA (Klavinskis et al. 1999; L.S. Klavinskis, C. Barnfield, and P. Hobson, 2000, unpublished observations). This may arise from the presence of physical and chemical barriers impeding transfection in the respiratory and gastrointestinal tract, including endonucleases, mucolytic enzymes, low pH, and turbulence. To increase plasmid DNA uptake and transfection efficiency, several approaches have focused on condensing (or encapsulating) the naked plasmid DNA with either cationic liposomes (Perrie et al. 2001), cytofectins based on cationic lipids (Klavinskis et al. 1999), cationic block co-polymers (Laus et al. 2001), or biodegradable microspheres such as poly (dl-lactide-co-glycolide: Herrmann et al. 1999; Kaneko et al. 2000). Bacterial systems including attenuated *Shigellla flexneri* and *Salmonella typhimurium*, which invade mucosal epithelial cells, have also been developed for oral delivery of DNA vaccines (Darji et al. 2000; Shata and Hone 2001). Detailed discussion of these systems lies outside the focus of this chapter.

GENERATION OF IMMUNE RESPONSES BY NAKED DNA VACCINES

Plasmid DNA uptake

The precise mechanism by which naked plasmid DNA enters cells and is translocated to the nucleus to initiate transcription is not fully understood. Evidence from electron micrographs suggests that plasmid DNA is internalized by electrostatic binding to the cell membrane and endocytosed via clathrin-coated pits (Figure 2) (Zabner et al. 1995; Friend et al. 1996). Direct fusion with the cell membrane and/or fluid phase endocytosis (macropinocytosis: Apodaca 2001) may also contribute to cellular uptake of plasmid DNA (Figure 2). Endosomal uptake of plasmid DNA can be increased by complexing the DNA with cationic liposomes, cytofectins, or ligands to cell surface receptors (Fasbender et al. 1997; Harbottle et al. 1998; Klavinskis et al. 1999; Perrie et al. 2001). Once plasmid DNA is internalized, rapid escape from the endosome is critical to the efficiency of plasmid-encoded antigen expression. Endosomes mature through various stages of acidification and eventually fuse with lysosomes containing enzymes, which degrade DNA. Release of plasmid DNA from the endolysosome is thought to be a consequence of membrane disruption. Cationic lipids or peptides (e.g. from the hemagglutinin of influenza virus) that fuse with the endosomal membrane have been reported to increase transfection efficiency (Fasbender et al. 1997; Zhang et al. 2001). Despite these modifications, only a fraction of internalized plasmid DNA penetrates the cytoplasm. Plasmid DNA is prone to further degradation by cytosolic nucleases. Thus, only a very small proportion of transfected DNA is available for transport across the nuclear membrane (reviewed by Johnson-Saliba and Jans 2001). The size of plasmid DNA vectors (2–10 MDa) is generally assumed to preclude efficient diffusion across the nuclear pore complex, thus compounding the inefficiency of plasmid DNA transfection. After transcription, mRNA is translated and plasmid-encoded protein within the cytoplasm is accessible to the TAP-dependent MHC-I-processing pathway. The induction of immune responses by DNA vaccines is all the more remarkable in view of the multiple cellular barriers that impede efficient transfection of plasmid DNA and attests to the importance of the adjuvant activity of CpG DNA.

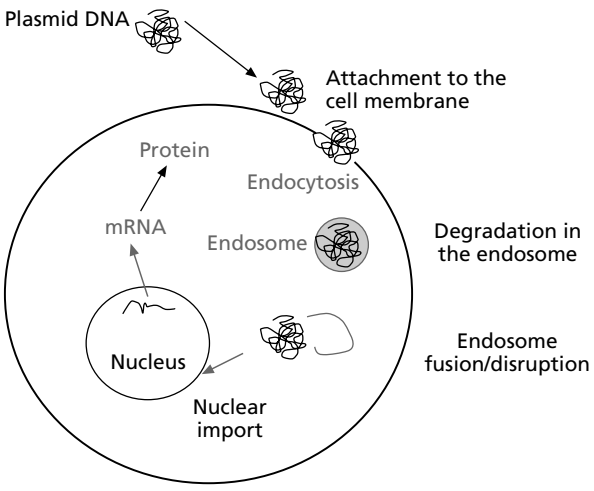

Figure 2 *Schematic representation of critical steps in the cytosolic synthesis of plasmid encoded antigen after membrane binding of plasmid DNA.*

Processing and presentation of plasmid DNA-encoded antigen

For the presentation of plasmid DNA-encoded antigen to B cells, it appears that, as long as antigen is accessible to the B-cell receptor, the nature of the transfected cell exporting the plasmid DNA-encoded protein is immaterial (Loirat et al. 1999; Armand et al. 2000). For DNA vaccines expressing purely cytosolic proteins, it had been suggested that antigen release to the extracellular milieu might be effected by CTL lysis of the transfected cell. However, recent data indicated that neither perforin nor $CD8^+$ T-cell-mediated lysis is required for priming $CD4^+$ T-cell or antibody responses (Hassett et al. 1999).

For the priming of $CD8^+$ T-cell responses there are at least three mechanisms by which a plasmid DNA-encoded antigen may be processed and presented. These include: (1) direct transfection and priming by somatic cells (such as myocytes, fibroblast, and keratinocytes); (2) crosspriming, whereby antigen is transferred from transfected somatic cells to professional APCs; or (3) direct transfection of APCs.

DIRECT PRIMING BY SOMATIC CELLS

The seminal observation that intramuscular injection of plasmid DNA-induced protein expression in muscle (Wolff et al. 1990) and elicited strong $CD8^+$ CTL responses in mice (Ulmer et al. 1993) suggested that muscle cells were critically involved in the initiation of CTL responses. In support of this premise, it was shown that adoptive transfer of stably transfected myoblasts expressing influenza nucleoprotein into mice was sufficient to induce $CD8^+$ CTLs and protect from virus challenge (Ulmer et al. 1996). This provided compelling evidence that antigen expression by muscle cells was sufficient to prime for CTL-mediated protection. It was unresolved whether CTL responses were directly induced by myocytes expressing the encoded antigen or they were indirectly induced through antigen transfer from myocytes to professional APCs. A conceptual difficulty with direct priming was that muscle cells do not express co-stimulatory molecules (CD80, CD86) essential to initiate T-cell responses and were therefore unlikely to act as APCs. To resolve the contribution of somatic versus bone-marrow derived APCs in CTL priming, bone-marrow-derived cells were adoptively transferred to irradiated F1 hybrid mice, to create bone marrow chimeras with somatic cells of both F1 MHC haplotypes and APCs of a single MHC haplotype of the donor bone marrow. Peptide-specific CTLs were induced only by immunization of mice with plasmid DNA encoding the peptide presented by the MHC-I molecules found on the donor bone marrow (Fu et al. 1997; Iwasaki et al. 1997). These studies demonstrated that bone-marrow-derived APCs play a dominant role in CTL priming and suggested that either APCs were directly transfected or antigens (or their epitopes) synthesized in somatic cells could be transferred to APCs (by crosspriming, see below) for presentation by MHC-I molecules.

CROSSPRIMING BY DNA VACCINES

Crosspresentation of antigenic material from apoptotic cells to DCs has been established as an important mechanism for the induction of $CD8^+$ CTL responses against tumor or pathogen-derived antigens (Bevan 1976). In vitro studies have established that this mechanism is distinct from the classic endogenous TAP-dependent pathway of MHC class I restricted peptide presentation. Several lines of evidence indicate that crosspriming also occurs after DNA immunization. Loirat et al. (1999) have shown that immunization with a plasmid DNA vector driven by a muscle-specific promoter elicited CTLs, despite expression of antigen restricted to muscle cells, suggesting that crosspresentation of antigen to APCs was involved. Second Corr et al. (1999) demonstrated, using a transactivating plasmid system and bone marrow chimeras, that CTL induction by plasmid DNA was critically dependent on antigen expression by somatic cells and transfer to APCs. However, a complementary mechanism involving direct transfection of APCs could not be excluded (see below). More recently, cross-presentation of antigen to DCs has been facilitated by constructing DNA vaccines, which induce apoptotic death of the antigen-expressing cell. Co-immunization with DNA vaccines that express Fas or a mutated version of a caspase gene that induces the creation of apoptotic bodies has been reported to enhance cell-mediated immunity (Chattergoon et al. 2000; Sasaki et al. 2001). The underlying mechanism by which antigen is transferred from somatic cells to APCs is not fully understood. Chaperones, including heat shock proteins 70 and 73 (hsp70, hsp73), have been implicated in the transfer of immunogenic material from plasmid DNA-transfected macrophages or somatic cells to DCs (Kumaraguru et al. 2000; Kammerer et al. 2002). The precise mechanism by which chaperone-bound peptides are released and cross-presented by DCs remains to be resolved. Candidate mechanisms include either a facilitated exchange or delivery system, whereby chaperone-bound peptide is internalized after receptor-mediated DC binding with peptide exchange between nascent MHC class I molecules and the chaperone (Figure 3a). Alternately, chaperone-bound peptide may be directly exchanged with cell-surface MHC class I bound peptide (Figure 3a).

DIRECT TRANSFECTION OF APCS BY DNA VACCINES

Although current data provide a compelling case for indirect CTL priming through crosspresentation, other studies provide evidence that APCs are directly transfected after DNA immunization. Removal of muscle (within 10 min) from the injection site of a DNA

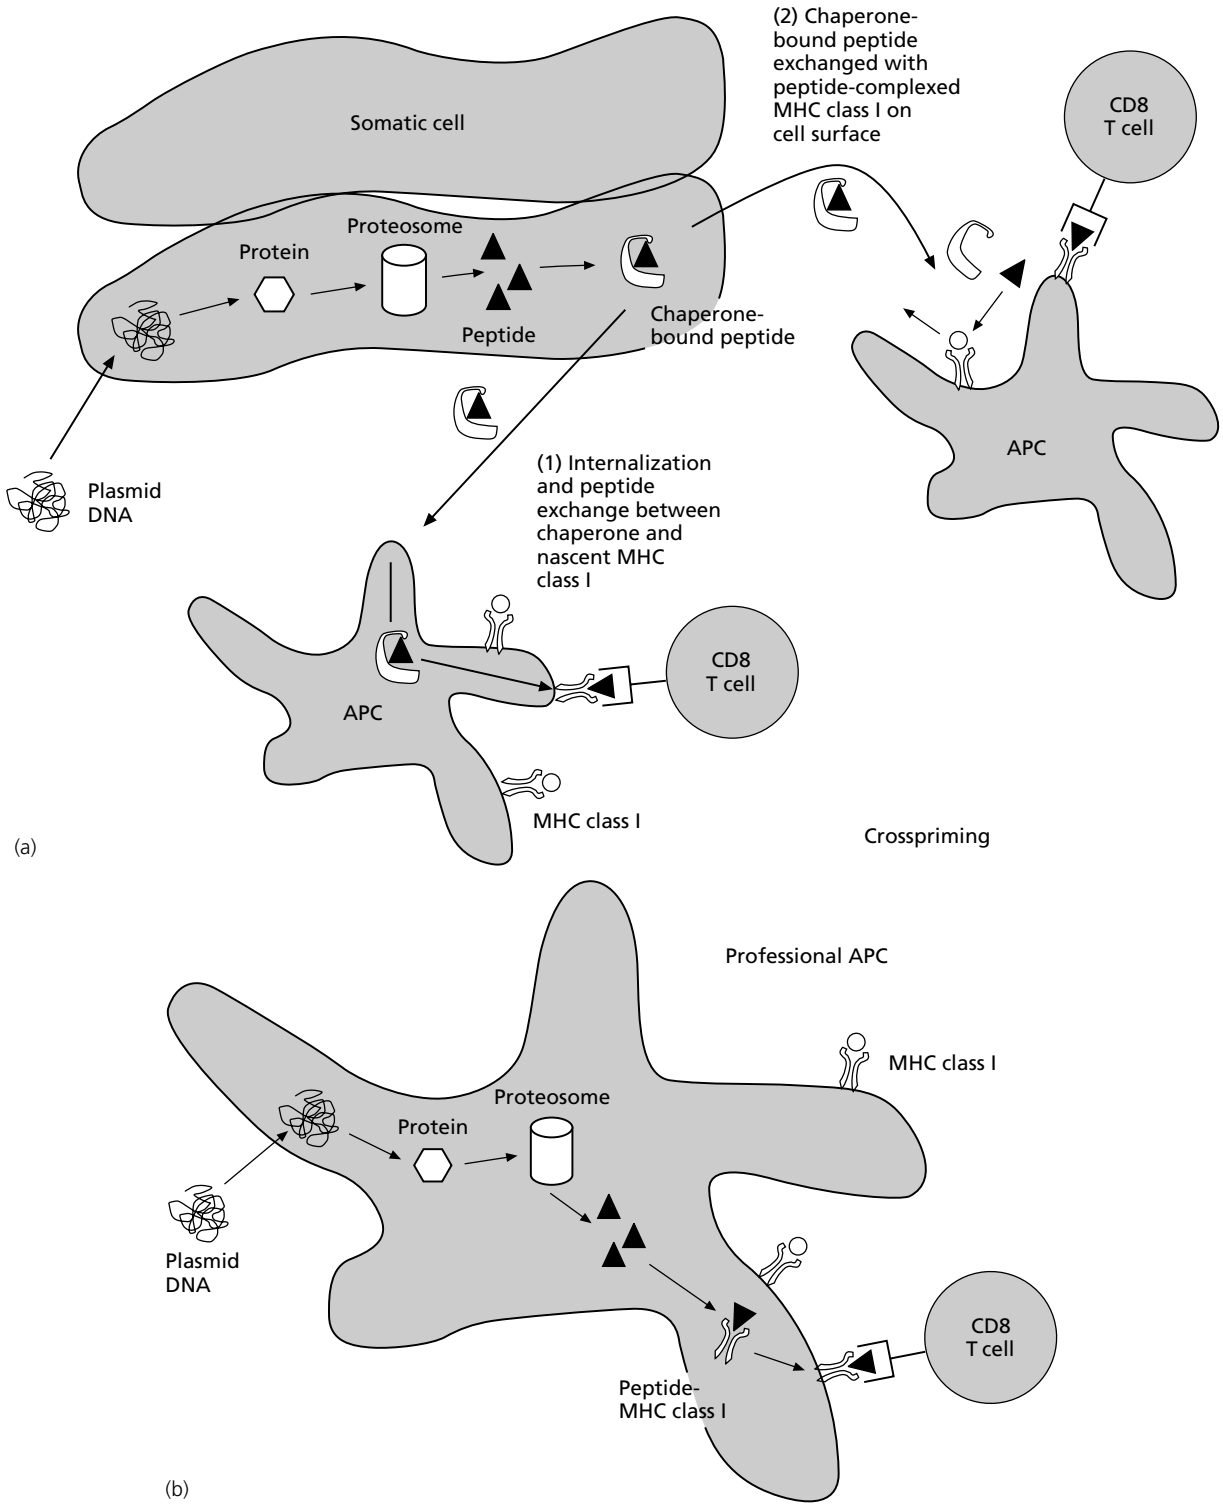

Figure 3 *Mechanisms of antigen presentation after DNA immunization.* **(a)** *Crosspresentation of antigenic material from plasmid DNA-transfected somatic cells to antigen-presenting cells (APCs) in vivo. Injection of plasmid DNA leads to transfection of somatic cells (muscle cells, keratinocytes or any MHC class II negative cells). Newly synthesized protein is targeted to proteosomes for proteolytic cleavage and peptide transport across the endoplasmic reticulum (ER). Chaperones, such as heat shock proteins, bind these peptides, which are crosspresented by MHC-I molecules on professional APCs to CD8$^+$ T cells. The precise mechanism is unclear but may involve either (1) receptor-mediated internalization of peptide bound chaperone and peptide exchange between the chaperone and newly synthesized MHC class I or (2) peptide exchange between cell surface MHC class I and chaperone-bound peptide.* **(b)** *Direct transfection of bone marrow-derived APCs. Injection of plasmid DNA leads to direct transfection of a small number of dendritic cells. Peptides generated* in situ *are presented by MHC class I molecules to CD8$^+$ T cells*

vaccine did not alter the magnitude or quality of the subsequent immune response, suggesting that transfection of cells (possibly APCs) distal to the injection site is sufficient to prime for CTLs (Torres et al. 1997). Antigen and reporter genes have been demonstrated in macrophages, Langerhans' cells, and DCs present both at the site of DNA vaccine delivery and in draining lymph nodes (Chattergoon et al. 1998; Akbari et al. 1999; Barnfield et al. 2000). This suggests that APCs are transfected in situ and migrate to draining lymph nodes or alternately are transfected within lymph nodes after lymphatic drainage of plasmid DNA (Figure 3b). Conclusively, plasmid-encoded mRNA has been demonstrated in isolated DCs after either intradermal or mucosal DNA vaccine delivery (Bouloc et al. 1999; Barnfield et al. 2000). Functional studies have demonstrated that DCs isolated from plasmid DNA injected skin or nasal tissue were able to stimulate the proliferation of T-cell responses in vitro (Bouloc et al. 1999; Barnfield et al. 2000). Second, DCs isolated after DNA immunization were shown to prime for CTL responses in naïve mice following adoptive transfer (Bouloc et al. 1999). These reports indicate that different routes of DNA vaccine delivery result in direct transfection of APCs and lead to induction of CTL responses. Current evidence suggests that the efficiency of DC transfection in vivo is very low (Barnfield et al. 2000). However, considering the potent stimulatory activity of DCs (reviewed by Steinman and Poe 2002), large numbers of transfected DCs may not actually be essential to elicit CTL responses. In support of this hypothesis, adoptive transfer of as few as 500–1000 in vitro transfected DCs to mice induced a comparable cellular and humoral immune response to that elicited by gene-gun immunization with the same antigen-encoding plasmid DNA (Timares et al. 1998).

In summary, two major pathways for CTL priming by DNA vaccines have been established. Enhancement of crosspriming has been established by co-delivery of plasmid DNA-encoding apoptotic proteins. Formulations or delivery systems that target APCs directly may also increase plasmid DNA uptake and CTL priming.

AUGMENTING THE IMMUNOGENICITY OF DNA VACCINES

Preclinical studies in several murine models of infectious disease have shown that DNA vaccines effectively elicit cellular and humoral immune responses, which confer protection from pathogen challenge (e.g. Ulmer et al. 1993; Li et al. 1998; Gebhard et al. 2000). Although these observations have been very encouraging, the magnitude of the immune responses induced in human and nonhuman primates by the first generation of naked DNA vaccines has proved lower than that achieved by attenuated or protein adjuvanted vaccines (see MacGregor et al. 1998; Amara et al. 2001). This difference in efficacy of DNA vaccines between species results partly from the higher level of protein expression achieved in mice after intramuscular injection than in other species (Jiao et al. 1992). Second, the dose of plasmid DNA injected in mice per kilogram body weight significantly exceeds the per kilogram dose administered to human and nonhuman primates, so comparisons of immunogenicity are not appropriate. Furthermore, murine cells reportedly demonstrate greater sensitivity than human cells to the adjuvant activity of CpG DNA (Bauer et al. 2001). Thus although naked DNA vaccines on their own may not be adequate to protect against disease in humans, technological developments in vector construction, incorporation of genetic or conventional adjuvants, deployment of novel delivery vehicles, or poxvirus booster inoculations (see below) may lead to the development of effective DNA vaccines.

Modification of the vector

PROMOTER

It is generally believed that the level of gene expression attained in vivo after DNA immunization correlates with the immune response generated. Therefore, approaches to improve gene expression may enhance DNA vaccine potency. Virally-derived promoters, including the most frequently used CMV immediate early enhancer–promoter, provide high levels of gene expression within mammalian cells (Manthorpe et al. 1993). However, these promoters are subject to transcriptional silencing, after CpG DNA-mediated activation of proinflammatory cytokines (Romero and Lavine 1996). Elimination or methylation of CpG motifs within the plasmid backbone reportedly increases the duration of antigen expression (e.g. Yew et al. 2001; Reyes-Sandoral and Ertl 2004). Although this modification may provide the longer-term expression required for gene replacement therapy, it needs to be balanced with the loss of adjuvant activity required for DC maturation and to initiate T-cell priming. Alternate promoters, including cell-specific, tissue-specific, and hybrid CMV promoters, have been evaluated (Xiang et al. 1997; Barnhart et al. 1998; Gebhard et al. 2000; Kwissa et al. 2000; Bonkobara et al. 2001). Plasmid vectors containing the human ubiquitin promoter could be particularly useful. Sustained, high-level gene expression has been achieved with this promoter in the presence of plasmid backbones containing CpG motifs (Yew et al. 2001).

CODON OPTIMIZATION

Optimizing codon usage for eukaryotic cells can also enhance expression of antigens. Codon bias has been observed in several species and may differ from the codons most frequently used by pathogens. Changes in codon usage, which modify RNA structure, have been shown to enhance the expression of HIV *env* and *gag* genes. In

mammalian cells the *env* and *gag* genes are made as long unspliced transcripts that contain overlapping reading frames with the small regulatory genes of HIV *rev* and *tat*. These transcripts are retained in the nucleus and are rapidly spliced in the absence of *rev*, thus preventing the transport of full-length message to the endoplasmic reticulum (ER). The transcripts are inhibited from transport to the ER by *rev*-dependent sequences that are themselves part of the structural gene sequence. Structural modification of the RNA through changing codon usage has led to an increase in HIV *envelope* and *gag* expression with an increase in anti-HIV gp160 CTLs and antibody reported (Andre et al. 1998; Vinner et al. 1999).

Modification of the inserted gene

By altering the cellular location where antigen is expressed or by the inclusion of protein sorting or targeting sequences, DNA vaccines have been modified either to increase priming for $CD8^+$ T-cell responses or to enhance B-cell activation. The addition of N-terminal ubiquitin sequences has been reported to lead to an increase in CTL precursor frequency and a reduction in antibody responses (Wu and Kipps 1997; Rodriguez et al. 1998). This is most probably the result of enhanced targeting of *de novo* synthesized cytosolic proteins to the proteosome (an organelle in which the protein is hydrolyzed to short peptides for TAP-dependent entry into the ER and MHC-I presentation). Proteins are thus rapidly processed to short peptides, which precludes or reduces the release of native protein for efficient antibody production. Another approach has been to design vectors that incorporate the E3 leader sequence from adenovirus, which facilitates transport of antigens from the cytosol directly into the ER for binding to MHC-I molecules. The addition of the E3 leader sequence has been reported to increase CTL responses to certain (Ciernik et al. 1996; Iwasaki et al. 1999), but not all (Ciernik et al. 1996), plasmid DNA-encoded antigens. Similarly, immunization with plasmid DNA encoding an antigen fused C terminally to a truncated cytosolic chaperone (heat shock protein 73 or hsp73) has been reported to increase CTL induction by bypassing the normal proteosome/TAP route of peptide entry into the ER (Kammerer et al. 2002). The stable *de novo* expression of antigen with hsp73 in the cytosol from a DNA vector may facilitate crosspresentation of antigen to DCs in vivo.

$CD4^+$ T-cell responses can be augmented by addition of sorting signals from membrane proteins, which are normally targeted to the lysosomal compartment, thereby directing plasmid-encoded proteins toward the MHC-II antigen-presentation pathway (Langlade-Demoyen et al. 2003). The immunological consequence of lysosomal targeting appears variable and depends on the primary sequence of the encoded antigen (Rodriguez et al. 2001). Plasmid DNA-encoded $CD4^+$ T-cell epitopes, which contain cleavage sites for the lysosomal endopeptidase (cathepsin D), were destroyed when targeted to lysosomes.

Humoral immune responses can be enhanced by the addition of a signal sequence fused to the antigen-coding sequence to direct protein transport through the ER and export from the cell surface (Lewis et al. 1999). Thus, synthesized protein bypasses the normal proteosome/TAP route of peptide delivery into the ER and is secreted for B-cell binding. Immune responses in mice immunized with a secreted form of antigen demonstrate an enhanced serum IgG1 response and increased levels of IL-4 by antigen-restimulated lymph node T cells in vitro (Lewis et al. 1999).

DNA delivery

The distribution of plasmid DNA from the site of vaccine delivery and efficiency of cellular uptake are key factors limiting the potency of DNA vaccines. One approach to increase DNA delivery is in vivo electroporation. A low intensity of electric pulses (100–200 V/cm) delivered from electrodes applied to the muscle or skin has resulted in significant enhancement in the cellular and humoral immune responses generated to injected DNA vaccines (Kadowaki et al. 2000; Widera et al. 2000). The wide-scale feasibility, user friendliness, and safety of this immunization approach remains to be established. The potential for DNA integration into host genomes is a concern, because electroporation results in a much larger copy number of copies of plasmid DNA per cell than achieved by injected naked plasmid DNA (Dupuis et al. 2000).

An alternate approach to increase DNA vaccine delivery is through formulations designed to protect plasmid DNA from degradation and to increase the release of plasmid DNA from the endosomal compartment and entry into the nucleus. Various liposomes, cationic lipids, and cationic block polymers (polycations combined with hydrophilic nonionic polymers) were initially developed to enhance therapeutic gene therapy (reviewed by Lechardeur and Lukas 2002). Several groups have since demonstrated that cationic lipid or polymer-complexed plasmid DNA also enhanced the induction of cellular and humoral immune responses (Klavinskis et al. 1999; Hartikka et al. 2001; D'Souza et al. 2002). There is some evidence to indicate that these formulations (or cytofectins) may not only increase plasmid DNA uptake but also synergize with bacterial CpG to activate the innate response and augment T-cell priming by DNA vaccines. Lipid-complexed plasmid DNA has been reported to increase DC activation and increase proinflammatory cytokine (IL-12 and IFN-γ) production at the site of plasmid DNA delivery (Freimark et al. 1998; Barnfield et al. 2000). Lipid-complexed plasmid DNA may (like liposome-complexed antigens) demonstrate preferential uptake by APCs.

Another approach to augmenting the immunogenicity of plasmid DNA-encoded antigens has been the use of biodegradable polymeric microparticles. Plasmid DNA encapsulated by the polymer poly(lactide-co-glycolide) (PLG) can be delivered by systemic and mucosal routes and has been reported to elicit immune responses (Chen et al. 1998; Kaneko et al. 2000) that confer protection in a murine rotavirus challenge model (Chen et al. 1998). Adsorption of plasmid DNA on to pre-formed PLG microparticles has also been shown to prime for both antibody and cellular immune responses (Singh et al. 2000). PLG-mediated vaccine delivery appears to act, in part, by targeting PLG-containing microspheres to APCs, rather than achieving an increase in gene expression (Singh et al. 2000).

Genetic adjuvants for DNA vaccines

Several groups have used plasmid DNA encoding various cytokine, chemokine, or co-stimulatory molecules to enhance or polarize the type of immune response generated by DNA immunization (summarized in Tables 1 and 2). In some instances the outcome attributed to a particular immunomodulator has been inconclusive or variable depending on the antigen, mouse strain, or plasmid vector used. The variability in response may also reflect the complexity of effects attributed to an immunomodulator and those elicited in response to bacterial components of the vaccine vector (described earlier). Co-immunization with plasmid DNA encoding Th1 cytokines, IL-12, IL-18, IFN-γ, and TNFα or the chemokines granulocyte–macrophage colony-stimulating factor (GM-CSF) or RANTES with antigen-coding DNA vaccine constructs has resulted in enhanced CTL and/or Th-cell proliferative responses (summarized in Tables 1 and 2). Co-immunization with plasmid DNA encoding IL-12 also appears to prolong the duration of the CTL response (Chattergoon et al. 2004). Conversely, co-immunization with plasmid DNA encoding certain Th2 cytokines (e.g. IL-4, IL-5, IL-6), or IL-2, IL-15, IL-18, or GM-CSF, has been reported to augment humoral immune responses (Table 1).

Other investigators have targeted transgene products to lymph nodes or APCs by constructing DNA vaccines encoding secreted fusion proteins that contain CTLA-4, L-selectin, or CD40L, the cognate ligands of which are present on APCs. By targeting secreted antigens for APC uptake, stronger immune responses have been reported (Mendoza et al. 1997; Boyle et al. 1998; Sin et al. 2000). Similarly, expression of plasmid DNA-encoded co-stimulatory molecules (CD80 or CD86) on transfected somatic or APCs can provide critical secondary signals for T-cell activation, through ligation of cognate receptors (CD28/CTLA-4). A number of studies have reported that co-administration of plasmid DNA-encoding antigen and CD80 or CD86 increased T-cell responses without any change in the humoral immune response (Iwasaki et al. 1997; Kim et al. 1997).

Table 1 *Modulation of DNA vaccines by co-delivery of cytokines and chemokines*

Cytokine	Antibody	Cellular response	CTLs	Reference
Chemokine

PRIME-BOOST APPROACHES

The relative lack of effectiveness of DNA vaccines in nonhuman primates has led to the development of heterologous immunization regimens, where the immune response induced by plasmid DNA is enhanced by a boost from a heterologous vector or protein. Strategies have included priming with a DNA vaccine and boosting with a recombinant protein-adjuvanted vaccine. Enhancement in the humoral immune response has been demonstrated with variable protection of nonhuman primates from pathogen challenge (Letvin et al. 1997; Putkonen et al. 1998; Cherpelis et al. 2001). Superior CTL responses in nonhuman primates against antigens from HIV, simian immunodeficiency virus (SIV), Ebola virus, and malaria have been demonstrated where DNA vaccines were used as priming agents and augmented by various viral vectors, such as fowlpox viruses (Kent et al. 1998; Robinson et al. 1999), vaccinia virus (Sedegah et al. 2000), modified vaccinia Ankara (MVA: Scheider et al. 1998; Hanke et al. 1999; Allen et al. 2000; Mwau et al. 2004), or adenovirus (Sullivan et al. 2000; Shiver et al. 2002). The superiority of the DNA prime-viral vector boost approach may reside in the ability of the DNA vaccine component to focus the immune response on to a single antigen, without competition from the myriad of viral vector-encoded antigens. The relative inefficiency of DNA vaccines to boost immune responses primed by viral vectors is most probably the result of the small amount of antigen generated and the weak induction of immunomodulatory cytokines and chemokines required to trigger expansion of antigen-specific memory cells.

SAFETY CONSIDERATIONS FOR VACCINE ADMINISTRATION IN HUMANS

To date, DNA vaccines have been shown to be well tolerated in both preclinical and phase 1 clinical trials (see below). Immunopathological reactions such as inflammation and general immunosuppression have not been observed, although a number of safety concerns remain. These include: (1) the possibility that DNA vaccines could integrate into the host genome, which could result in the activation of oncogenes or the inactivation of tumor suppressor genes; (2) the induction of responses against self-antigens expressed on transfected cells and that initiate autoimmune disease; (3) the induction of tolerance rather than active immunity to plasmid DNA-encoded antigens; and (4) the stimulation and production of antibodies to the injected DNA.

Potential for integration

The primary safety concern of plasmid DNA vaccines is their potential to integrate into the genome of host cells. This could increase the risk of malignancy by causing either the activation of oncogenes or inactivation of tumor suppressor genes. If integration occurs in germline cells, there is also a potential for germline transmission. These concerns stem from the knowledge that plasmids can integrate at a very low level into cellular DNA when transfected into actively dividing cells. However, it is believed that only a small fraction of integration events would alter a gene and prove harmful to a host cell. The probability of integration in vivo is likely to be further reduced by physical–chemical barriers that impede efficient uptake of plasmid DNA in vivo, including exonucleases, interstitial DNA-binding proteins, and a lower rate of cellular proliferation than cells in vitro synchronized for transfection under S-phase conditions. Despite concerns raised, there is no clear evidence to date that naked DNA vaccines can integrate. Gel-purified genomic DNA isolated from many tissues (including germline) following intramuscular injection of plasmid DNA and assayed by polymerase chain reaction (PCR) has produced no evidence of integration to a detection sensitivity of one copy plasmid per microgram of DNA (Ledwith et al. 2000; Schattenberg et al. 2000a). This rate is at least three orders of magnitude lower than

the theoretical frequency of spontaneous gene-inactivating mutations (Nicols et al. 1995). Thus, for plasmid DNA vaccines delivered by intramuscular injection, the risk of mutation caused by integration appears to be negligible. Other methods of plasmid DNA delivery (including gene gun or electroporation), or use of novel formulations or adjuvants that increase the efficiency of cell transfection, could potentially influence the integration frequency. Indeed compelling evidence for integration of plasmid DNA following electroporation has recently been reported (Wang et al. 2004).

Potential for induction of immunological tolerance or autoimmunity

Most vaccines intended for human use are administered to infants and young children. As a result of the immaturity of their immune system, there is a potential risk that exposure to DNA vaccines during the neonatal period may induce tolerance rather than immunity. As protein encoded by a DNA vaccine is produced endogenously and expressed in the context of self-MHC, the potential exists for the neonatal immune system to recognize the encoded antigen as 'self', resulting in tolerance rather than immunity. Consistent with this possibility, in one report a plasmid DNA vaccine encoding the circumsporozoite protein (CSP) of malaria induced long-lasting tolerance when administered to newborn but not adult mice (Ichino et al. 1999). Co-administration of plasmid DNA encoding GM-CSF prevented the development of neonatal tolerance in this model (Ishii et al. 1999). The simplest explanation appears to be that, although CpG motifs associated with plasmid DNA are responsible for the activation of DC, additional maturational signals may be required to optimize the response to certain DNA vaccines in neonates. Nevertheless, most studies performed to date in rodents and nonhuman primates have demonstrated induction of significant cellular and humoral immunity in neonates (Manickan et al. 1997; Prince et al. 1997; Sarzotti et al. 1997; Bot et al. 1998). Increasing the content of CpG oligonucleotides or co-administration of plasmid DNA-encoding, Th1-driving cytokines (IL-12 or IFN-γ) has augmented Th1-type responses where additional DC maturational signals were found to be required in neonates (Kovarik et al. 1998). Overall, neonatal DNA vaccines, rather than proving tolerogenic, are substantially more effective in inducing Th1 responses than conventional vaccines.

Another theoretical concern is that autoimmune responses could occur as a result of immune-mediated destruction of plasmid DNA-transfected cells expressing antigen. Cytolysis of antigen-expressing cells would release self-antigens for uptake and presentation by DCs, theoretically capable of initiating autoreactive T- and B-cell responses. However, presentation of self-antigen occurs during normal cell turnover and in the course of viral and bacterial infections, without pathological sequelae. In this respect, it appears unlikely that DNA vaccines would pose any greater risk in initiating organ-specific autoimmunity than conventional viral or bacterial vaccines. A theoretical concern that has not been addressed to date is the ability of DNA vaccines to induce responses to cryptic or subdominant epitopes, which theoretically may crossreact with 'self' and trigger potentially autoreactive T cells.

Potential for induction of anti-DNA antibodies

Concerns that DNA vaccines may promote the development of autoantibodies to double-stranded DNA (dsDNA) (believed to be the hallmark of autoimmune disease such as systemic lupus erythematosus (SLE)) arise from a series of observations. Bacterial DNA has been reported to induce anti-dsDNA antibodies in normal mice and to accelerate the development of autoimmunity in strains genetically predisposed to lupus disease (Gilkeson et al. 1993). Bacterial CpG can also stimulate the production of IL-6, block apoptosis of activated lymphocytes, and block the suppressive effect of regulatory T cells (Krieg et al. 1995; Klinman et al. 1996; Pasare and Medzhitov 2003), mechanisms that may facilitate the persistent activation of B cells and predisposition to the development of SLE. Although an increase in IgG anti-DNA-secreting cells has been reported immediately after repeated immunization of normal mice with plasmid DNA, the increases were small when compared with the spontaneous production of autoantibodies reported in lupus-prone mice (Mor et al. 1997). Furthermore, the transient increase in serum IgG anti-DNA reported did not result in either the development of disease in normal mice or acceleration of disease in lupus-prone strains of mice (Mor et al. 1997). Although the possibility remains that a subset of DNA vaccines encoding determinants crossreactive with self-antigens may stimulate an autoimmue response, current data suggest that the level of anti-DNA antibody induced by plasmid DNA is unlikely to induce systemic autoimmune disease.

CLINICAL TRIALS

The first clinical trials were designed to determine whether DNA vaccines were safe, well tolerated, and immunogenic in normal healthy adults. A naked anti-malaria DNA vaccine administered by the intramuscular route was well tolerated up to a 2.5 mg dose and induced CTLs in 11 of 17 individuals, in the absence of detectable antibody (Wang et al. 1997). Pilot studies with an HIV *env/rev* and an HIV *gag/pol* DNA vaccine administered by the intramuscular route also demonstrated that weak T-cell responses were induced in the absence of adverse

local or systemic effects at doses as high as 3 mg (Boyer et al. 2000; Tellez et al. 2000). A candidate HIV-1 clade A (HIVA) DNA vaccine (containing more than 25 HIV CTL epitopes fused in tandem to the HIV *p17* and *p24* gene) has undergone phase 1 clinical trials in the UK and Kenya. The vaccine appears to be well tolerated and CTL responses have been detected in a number of vaccinees (McMichael et al. 2002). Ongoing studies, sponsored by the UK Medical Research Council and the International AIDS Vaccine Initiative (IAVI) are testing an HIVA DNA vaccine augmented by an MVA boost (coding the same HIV epitopes). Data reported from individuals receiving the combination vaccine are encouraging for the prime-boost approach and indicate that eight out of nine volunteers elicited CTL responses after the boost (McMichael et al. 2002; Mwau et al. 2004). Similar findings have been reported from a phase 1 trial of an HIV clade B *gag* DNA vaccine boosted with an adenoviral vector encoding the cognate HIV antigens (Emini 2002).

CONCLUSIONS

DNA vaccines have advanced rapidly in the past 10 years from laboratory phenomena into clinical trials. We now have a broader understanding of how they work and the limitations of the first generation of naked DNA vaccines in nonhuman primates, and have an appreciation of their safety profile. Several promising technologies are under development for increasing DNA vaccine potency. Data from the preliminary phase 1 clinical trials are encouraging and indicate that DNA priming followed by recombinant virus boost works significantly better than naked DNA alone. As newer technologies proceed into the clinic, the true potential of this vaccine technology will be established.

Adjuvants and subunit vaccines

GIUSEPPE DEL GIUDICE AND RINO RAPPUOLI

Adjuvants	2	Acknowledgments	17
Subunit vaccines	8	References	17

Adjuvants are substances that, when used in combination with vaccine antigens, induce a stronger and more effective response to the vaccine compared with that induced by the vaccine alone. Most vaccines currently used, especially those consisting of inactivated (killed) microorganisms and those containing purified molecules, are given together with adjuvants. Despite the major efforts made in the past decades to develop new vaccine adjuvants (Edelman 2000), the first adjuvants ever reported in the scientific literature, i.e. aluminum salts, still remain the standard adjuvants licensed for use in human beings.

The development of aluminum salts as the first adjuvants and the development of the first subunit vaccines are strictly linked together. An ideal subunit vaccine is a vaccine that contains the microbial antigen(s) critical in the pathogenesis of the infection, against which we want to induce a protective immune response. Thus, historically bacterial toxins in their inactivated forms remain the first subunit vaccines ever developed. This was made possible by the demonstration of the antitetanus immunity conferred to rabbits by immunization with attenuated tetanus toxin (von Behring and Kitasato 1890), and by the demonstration that formalin treatment fully inactivated the diphtheria toxin and guinea-pigs immunized with the formalin-treated toxin were protected against a lethal challenge (Glenny and Hopkins 1923; Ramon 1923). The first attempts to enhance the immunogenicity of these toxoids in animals were reported by Ramon (1925), who observed that the highest antibody titers were obtained in animals in which local inflammatory reactions were induced by the concomitant injection of other substances, such as sterilized tapioca, aluminum salts, lanolin, tannin, kaolin, etc. The use of aluminum hydroxide as an adjuvant to increase the immunogenicity of the diphtheria toxoid was introduced the following year by Glenny et al. (1926).

The approaches toward the development of new vaccines foresee, more and more, the use of purified components of the microorganisms, as native or recombinant proteins, or as synthetic peptides, either alone or conjugated to bacterial poly- or oligosaccharides. These highly purified proteins are less immunogenic than the traditional toxoids and inactivated vaccines, which contain impurities and are much less characterized at the molecular level. Thus, for new generation vaccines adjuvants stronger than aluminum salts are required to induce appropriate effective protective immunity. The correct construction of the vaccine molecule and the use of an appropriate adjuvant system will also be crucial for the induction of the most suitable immune effector mechanisms necessary to confer protection. We had to wait until the second half of the 1990s to see new vaccine adjuvants being approved for use in human beings. Several reasons may have limited the adoption of new vaccine adjuvants (Del Giudice et al. 2001b), among which are safety issues, and the appropriateness of a given adjuvant for the particular vaccine in terms of physical interaction, quality of the effector immune response to induce, and route of immunization that one wants to use. There is, however, hope that research now in progress will result in the development of new adjuvants to be used with existing vaccines, or with newly developed subunit vaccines.

ADJUVANTS

General considerations on mechanisms of action and routes of delivery

Despite the fact that vaccine adjuvants have been in use for more than 70 years, very little is known about the exact mechanisms involved in their biological effects. The depot effect postulated for aluminum salts and other adjuvants cannot by itself explain all the immunological phenomena that are triggered by vaccine adjuvants and bring about the activation and recruitment of professional antigen-presenting cells (APC) which, in turn, induce activation and expansion of antigen-specific T- and then of B-cell populations. The depot effect of aluminum salts, resulting in a reduced rate of antigen clearance from the site of injection, was first suggested by Glenny et al. (1931). However, a large series of experimental data has clearly shown that a slow release of the vaccine over time is very unlikely to contribute to the adjuvanticity of aluminum compounds (Gupta et al. 1996). Very many adjuvants, including aluminum salts, have been postulated to exert their adjuvanticity through their ability to activate APCs and increase the expression of major histocompatibility complex (MHC) class II molecules and several co-stimulatory molecules (Ulanova et al. 2001); however, the exact mechanisms leading to these phenomena are still unclear.

Over the past few years, there have been major advances in the field of innate immunity (Janeway and Medzhitov 2002) which have led to the recognition of several molecules and their relevant ligands as important elements in first-line defense against invading microorganisms. These findings are turning out to be instrumental in understanding the mechanisms of adjuvanticity of several substances, mainly those derived from bacterial components. The family of Toll-like receptors (TLR), first described in *Drosophila*, is emerging as a key player in the delivery of initial signals not only by invading pathogens, but also by some of their components, which may eventually be used as vaccine adjuvants.

Activation of cells by bacterial lipopolysaccharide (LPS) requires the presence on APCs of an intact TLR4: this will induce the expression of inflammatory cytokines and co-stimulatory molecules (Medzhitov et al. 1997). In addition to LPS, TLR4 is also implicated in the recognition of the heat shock protein (HSP) of 60 kDa (hsp60) (Ohashi et al. 2000) and lipoteichoic acid (Takeuchi et al. 1999), which have been known for some time to have adjuvant activity (Edelman 2000).

By forming heterodimers with TLR1 and TLR6, TLR2 recognizes several microbial components, such as peptidoglycan, bacterial lipoproteins, and zymosan (Aliprantis et al. 1999; Brightbill et al. 1999). It is likely that the strong adjuvant activity of complete Freund's adjuvant, which contains mycobacteria, and of monophosphoryl lipid A (MPL), derived from the bacterial cell wall, may be at least partly explained by the interaction with TLR2.

Finally, the strong immunostimulatory effect of unmethylated CpG DNA oligodeoxynucleotides (see below and see Naked DNA vaccines), which leads to strong induction of a T-helper (Th) 1)-type response, has been shown to be mediated by the specific recognition of TLR9 by these motifs (Hemmi et al. 2000). This leads to activation of macrophages and dendritic cells (DC), upregulation of MHC class I molecules and co-stimulatory molecules, and the production of proinflammatory (Th1-type) cytokines.

Several adjuvants do not, however, contain any microbial components and, thus, there is no indication that their mechanism(s) of action is mediated by interactions with TLR, e.g. it is very unlikely that aluminum salts exert their adjuvanticity through a TLR, because aluminum hydroxide behaves as a good adjuvant in genetic knockout mice lacking MyD-88, an adaptor molecule in the TLR-signaling pathway (Schnare et al. 2001).

Another point deserves comment. It is now very well known that adjuvants can profoundly affect the polarization of the T-cell response (and thereby of the effector – and possibly protective – immune response) induced by vaccines. Just to give a few examples, it is known that aluminum adjuvants can induce, in animals and humans, the production of antigen-specific IgE antibody (Nagel et al. 1979; Gupta and Relyveld 1991). This is very probably mediated by the high propensity of aluminum salts to polarize the $CD4^+$ T-cell response toward a Th2-type response, through an increased expression of IL-4 (Ulanova et al. 2001). At the other extreme, there is the example of the unmethylated CpG DNA oligodeoxynucleotides (see below), which lead to an exquisite, strongly polarized $CD4^+$ Th1-type response. In addition, activation of antigen-specific cytolytic $CD8^+$ cells may require the use of other adjuvants and/or delivery systems, such as bacterial or viral delivery systems, immunization with naked DNA, lipidation of the antigen, etc., most of which are discussed in other chapters of this book (see The role of CD8 T cells in the control of infectious disease and malignancies; New vaccine technologies, and Live vaccine carriers), and will not be specifically covered here.

Finally, because of their intrinsic anatomical characteristics and being the portal of entry of most pathogens, mucosal surfaces represent ideal sites for vaccine delivery. Live-attenuated vaccines (e.g. polio and salmonella vaccines) are given orally. However, nonreplicating, purified antigens are poorly immunogenic when delivered mucosally and may even induce a state of tolerance. The best mucosal immunogens are those with an inherent ability to attach to epithelial cells, e.g. the *Escherichia coli* heat-labile enterotoxin (LT), cholera

toxin (CT), bacterial fimbriae, some lectins, etc. (De-Aizpurua and Russell-Jones 1988). The existing adjuvants and the vast majority of those under investigation are specifically designed for parenteral administration. It is thus clear that strong and safe adjuvants specifically designed for delivery of vaccines at the mucosal surface are strongly needed. A lot of exciting research is currently being devoted to this issue, and it is briefly summarized in this chapter.

New vaccine adjuvants

It goes without saying that vaccine adjuvants can be evaluated as such only when they are associated with a vaccine. Consequently, in the following sections, adjuvants are always discussed in the context of their use in association with specific subunit vaccines. Space limitations preclude detailed discussion of all adjuvants under experimental and clinical evaluation (Table 1 gives an overview). Experimental adjuvants, such as complete and incomplete Freund's adjuvants (Freund et al. 1937), are not considered because of the major safety issues linked to them, although vaccines adjuvanted with incomplete Freund's adjuvant have been developed for veterinary use (McKercher and Graves 1977), and some have even been employed in humans in the past (Salk et al. 1952). Major emphasis will be given to those innovative adjuvants that in recent years have successfully become a reality in the vaccine field and to those that are receiving more attention within the scientific community. Readers interested in more detailed, technical information on specific adjuvants not covered here are referred to the literature published in the past few years (Edelman 1997; O'Hagan 2000; O'Hagan et al. 2001; Kenney et al. 2002).

ADJUVANTS LICENSED FOR USE IN HUMANS

MF59

MF59 is an oil-in-water emulsion consisting of uniformly small (<250 nm in diameter) and stable droplets of the natural and fully metabolizable oil squalene (a natural metabolite of cholesterol and a normal component of cell membranes), which is stabilized by the addition of two emulsifiers (Ott et al. 2000). The adjuvant is very stable over several years at 4°C and exhibits high versatility because it can be successfully formulated with fully soluble antigens (e.g. viral recombinant antigens), hydrophobic proteins (e.g. the influenza virus hemagglutinin (HA)), and particulate antigens (e.g. the hepatitis B virus (HBV) surface antigen (HbsAg) containing the pre-S2 region).

The fine mechanisms of the adjuvanticity of MF59 are not fully understood yet. The depot effect does not appear to play a major role because the adjuvant does not affect the distribution of the co-injected vaccine antigen (Dupuis et al. 2000). Two days after intramuscular injection, MF59 localizes in cells with the characteristics of mature macrophages. This adjuvant clearly induces an influx of macrophages at the site of injection, which appears to depend on the presence of chemokine receptor 2 (Dupuis et al. 2001). Irrespective of the mechanism(s) of adjuvanticity, from the data available it is clear that MF59 preferentially polarizes the immune response toward a Th2-type functional phenotype, as evidenced by the preferential induction of antigen-specific IgG1 antibody and Th2-type cytokines such as interleukin 4 and 5 (IL-4 and IL-5), using a variety of model vaccines (Valensi et al. 1994; Singh et al. 1998).

The successful results obtained with this adjuvant in the preclinical setting were instrumental in the move toward clinical studies in humans which, as in the case of influenza, have led to the licensing of the MF59-adjuvanted vaccine. Indeed, MF59 strongly enhanced (from 5 to >100 times) the immunogenicity of flu vaccines in various animal species (Ott et al. 1995). It fully restored the ability of old mice to mount a strong antibody response to flu vaccine equal to that observed in young, fully immunologically competent mice (Higgins et al. 1996), and increased the protective efficacy of the vaccine, even at lower doses (Cataldo and Van Nest 1997). In addition, this enhanced response was not affected by pre-existing immunity against the influenza virus (Higgins et al. 1996). This is particularly important because flu immunization is carried out every year and pre-existing immunity can negatively influence the efficacy of subsequent immunizations. The very strong adjuvanticity of MF59 has also been demonstrated with several other viral and bacterial vaccines, not only in mice, but also in monkeys, e.g. MF59 induced up to a 127-fold increase of the immunogenicity of a Chinese hamster ovary (CHO) cell-derived HBV vaccine containing the pre-S2 region compared with conventional, alum-adjuvanted vaccine, with protective antibody titers persisting for several months (Traquina et al. 1996). Similarly, in baby baboons it dramatically enhanced the protective (bactericidal) antibody response after immunization of conjugate vaccines against *Haemophilus influenzae* type b (Hib) and *Neisseria meningitidis* group C (MenC) (Granoff et al. 1997). Finally, MF59 induced a strong and persisting antibody response against recombinant FimH from uropathogenic *E. coli* in cynomologus monkeys, which were protected against bacteriuria and pyuria induced by an infectious challenge (Langermann et al. 2000).

Conventional, nonadjuvanted influenza vaccines exhibit a 70–90 percent efficacy in young adults (Advisory Committee on Immunization Practices 2001). However, this efficacy dramatically drops in older individuals, with a prevention of the clinical illness in only 5–33 percent of the immunized patients (Strassburg et al. 1986), probably as a result of reduced immunogenicity of influenza vaccines in older individuals (Keren et al. 1988). It is thus clear that more efficacious, improved

vaccines against influenza are needed. When given to older people, the MF59 trivalent subunit vaccine against influenza exhibited a very good safety profile, with local reactions that were mild and of short duration and, importantly, did not increase after repeated immunizations in the following influenza seasons (Minutello et al. 1999; Podda 2001). A consistent finding of several clinical trials carried out was increased immunogenicity of the MF59-adjuvanted vaccine compared with the conventional vaccine, which was observed even after repeated immunizations (Minutello et al. 1999; Podda 2001). This confirmed the lack of interference by preexisting immunity previously observed in animals (Higgins et al. 1996). Two observations are of particular interest. First, a significant increased immunogenicity of the MF59-adjuvanted vaccine was observed in older participants with chronic diseases, such as respiratory and cardiovascular diseases, and diabetes mellitus. Second, the use of MF59 increased the immunogenicity to heterovariant strains of the influenza virus (Podda 2001). More recently, MF59 was shown to enhance dramatically the immunogenicity to an A/H5N3 antigen, from a potentially pandemic strain of influenza virus (Nicholson et al. 2001). This study clearly showed that protective antibody titers were reached with reduced amounts of flu antigens per dose if the adjuvant was used. In addition, the induced antibody persisted for a much longer time and was significantly boosted by a secondary immunization 16 months after the first (Stephenson et al. 2003).

The MF59-adjuvanted subunit vaccine against influenza is now licensed and available in most European countries. The clinical experience with the MF59 adjuvant is much wider than its use with the influenza vaccine. MF59 has been tested in formulation of vaccines against HBV, hepatitis C virus (HCV), herpes simplex virus (HSV), human papillomavirus (HPV), cytomegalovirus (CMV), human immunodeficiency virus-1 (HIV-1), and is being also tested in humans with bacterial vaccines (Podda and Del Giudice 2003). Two major findings from these studies should be highlighted. First, MF59 was shown to enhance strongly the immunogenicity of an HBV vaccine containing the pre-S2 region, conferring seroprotection to 89 percent of immunized patients already after the first dose of the vaccine (Heineman et al. 1999). Second, recombinant proteins from CMV and HIV-1 formulated with MF59 and given to toddlers (second year of life) and newborns (within the first 3 days of life) were more immunogenic and safer than the same vaccines given to adults (Borkowsky et al. 2000; Cunningham et al. 2001; McFarland et al. 2001; Mitchell et al. 2002). Furthermore, as in the case of flu vaccine, the use of the MF59 adjuvant allowed the use of a significantly reduced amount of vaccine to induce high antibody and cellular immune responses, compared with the same vaccine given with alum as adjuvant (Borkowsky et al. 2000).

Virosomes

Virosomes are spherical, unilamellar vesicles with a mean diameter of 150 nm containing 70 percent egg yolk phosphatidylcholine and 20 percent synthetic phosphoethanolamine. The influenza virus hemagglutinin (HA) and trace quantities of viral neuraminidase (NA) from the H1N1 A/Singapore 6/86 virus strain are intercalated within the phospholipid bilayer. The role of the HA in the preparation of these vesicles appears to be that of binding to sialic residues on the cells to enhance endocytosis and fusion of the virosome with endosomes, with the final objective of enhancing the uptake of the associated vaccine and its resulting immunogenicity (Gluck 1999).

Several vaccines have been formulated with virosomes and tested for their safety and immunogenicity in clinical trials in humans, among which are the inactivated hepatitis A virus (HAV) vaccine (Holzer et al. 1996), the influenza subunit vaccine (Conne et al. 1997), diphtheria and tetanus toxoids (Zurbriggen and Gluck 1999), and vaccine combinations (Mengiardi et al. 1995). Virosome-adjuvanted vaccines against HAV and influenza virus have been licensed in several countries. More recently this technology has been applied to the delivery of synthetic peptides from malaria parasites (Poeltl-Frank et al. 1999; Moreno et al. 2001) and from HCV (Hunziker et al. 2002), showing the possibility of inducing priming of peptide-specific cytotoxic T lymphocytes (CTL).

ADJUVANTS AT AN ADVANCED STAGE OF DEVELOPMENT

MPL, QS-21, and their association (AS02)

Monophosphoryl lipid (MPL) A is derived from the LPS of *Salmonella minnesota*. Its adjuvant activity seems to be mediated by its interaction with the TLR2. MPL appears to enhance the migration and maturation of DCs (De Becker et al. 2000) and to promote the generation of Th1-type responses, with enhanced expression of the B7.1 co-stimulatory molecule, and the production of IL-2, IFN-γ, and IL-12 (Moore et al. 1999). The preferential activation of Th1-type cells was also demonstrated in vivo using a 3-deacylated form of MPL. Indeed, immunization of cotton rats with a recombinant respiratory syncytial virus (RSV) chimeric glycoprotein (Prince et al. 2000) or a formalin-inactivated RSV vaccine together with MPL (Prince et al. 2001) significantly reduced the degree of Th2-mediated alveolitis and interstitial pneumonitis after challenge with infectious virus.

MPL has been tested in humans using vaccines against different pathogens, cancer, and allergies. However, probably as a result of not having a very strong intrinsic adjuvanticity and/or an appropriate safety profile, MPL is now being used mainly in association with other adjuvants. One of the best associations studied is with

aluminium salts (referred to as AS04, formerly SBAS4). This adjuvant combination enhanced the immunogenicity of HBV vaccine given to volunteers with different immunization schedules (Thoelen et al. 1998; Ambrosch et al. 2000). This vaccine, however, induced a higher local reactogenicity than the conventional alum-adjuvanted vaccine, and did not enhance the immune response in HLA-DQ2-positive participants, who are poor responders to the HBV vaccine (Desombere et al. 2002).

The other well-investigated association is the one with QS-21, referred to as AS02 and formerly SBAS2. QS-21 is an acylated 3,28-*o*-bisdesmodic triterpene saponin (M_r = 1990 Da) derived from the bark of the South American tree *Quillaja saponaria* Molina (Jacobsen et al. 1996). Tested in different animal models and also in several human trials with different vaccine constructs (against HIV-1, influenza, HSV, HBV, malaria, cancer, etc.), QS-21 appears to augment both Th1- and Th2-type responses (Moore et al. 1999) and to favor the in vivo priming of antigen-specific $CD8^+$ cytotoxic cells (Newman et al. 1997), although this last activity still remains controversial (Evans et al. 2001). In HIV clinical trials comparing different adjuvants, QS-21 was associated with moderate-to-severe local reactions (Keefer et al. 1997); it appears, however, that these can be reduced by decreasing the amount of adjuvant used.

The combination of MPL and QS-21 adjuvants in an oil-in-water formulation (AS02) has been clinically tested in tuberculosis, HBV, HPV, HIV-1, cancer, etc. (Kenney et al. 2002). The best experience of this adjuvant system is, however, with a malaria vaccine both in challenge trials and in efficacy trials in endemic areas. A recombinant *Plasmodium falciparum* circumsporozoite vaccine fused with HBsAg plus AS02 (referred to as RTS,S/AS02) protected six of seven immunized volunteers against a challenge with infectious sporozoites. Interestingly, in this study protection correlated well with anti-sporozoite antibody titers, and was not observed in volunteers immunized with the same vaccine formulated with the AS04 (MPL + alum) adjuvant system (Stoute et al. 1997). Six months after the last immunization specific antibody titers decreased to a half/third of the peak titers. After a new challenge with sporozoites, only two of the previously protected participants were still protected, and no correlation was observed between antibody titers and protection (Stoute et al. 1998). The immune response to the vaccine was clearly polarized toward a Th1-type functional phenotype (Stoute et al. 1998; Lalvani et al. 1999). In a subsequent challenge study in a larger number of participants receiving different immunization schedules, this vaccine exhibited an overall protective efficacy of 41 percent (Kester et al. 2001). When tested in malaria-endemic areas to evaluate its protective efficacy against natural *P. falciparum* infection, the RTS,S/AS02 vaccine showed a 34 percent efficacy (71 percent in the first week of follow-up, 0 percent in the last 6 weeks). After a fourth dose of the vaccine 1 year later, the efficacy was 41 percent (Bojang et al. 2001).

This adjuvant system is now under evaluation using other plasmodial antigens as vaccine candidates. An AS02-adjuvanted LSA-3-based vaccine conferred protection to chimpanzees against a sporozoite challenge (Daubersiers et al. 2000). However, an AS02-adjuvanted RTS,S vaccine containing the sporozoite protein TRAP was not efficacious in the human challenge model (Kenney et al. 2002).

ISCOMs and Iscomatrix

Immunostimulating complexes (ISCOM) are cage-like structures of about 40 nm diameter containing the saponin Quil A, cholesterol, and phospholipids. Antigens are incorporated within the ISCOM structure. However, not all antigens incorporate spontaneously into ISCOMs, unless extensive antigen modifications are introduced. Iscomatrix is totally identical to ISCOMs except for the fact that antigen is not incorporated, but simply mixed with the particles or chemically coupled to them (Barr et al. 1998; Sjolander et al. 1998; Sjolander et al. 2001). Interestingly, ISCOMs have been shown in different models to exert their adjuvanticity not only after parenteral, but also after mucosal, administration (Hu et al. 2001). The adjuvant effect of ISCOMs both parenterally and mucosally requires the induction of the production of IL-12. Indeed, their adjuvanticity is significantly reduced in IL-12 knock-out mice, but not in mice lacking the IL-6, IL-4, or IFN-γ receptors, or the inducible nitric oxide synthase (Grdic et al. 1999; Mowat et al. 1999; Smith et al. 1999). It has been proposed that ISCOMs act by specifically targeting adjuvant and antigen to APCs, such as macrophages and/or DCs (Mowat et al. 1999). This peculiar targeting property may allow the antigen to enter the route of antigen processing that will result in the presentation of relevant epitopes within the context of MHC-I antigens, thus leading to the priming of antigen-specific MHC-I-restricted $CD8^+$ CTLs. Indeed, this is certainly the case in mice (Sambhara et al. 1998) and priming of CTL responses has also been shown in monkeys (Sjolander et al. 2001). The induction of a strong and long-lasting CTL response has been shown in rhesus monkeys immunized with the core protein of HBV adsorbed on to Iscomatrix (Polakos et al. 2001). In this and other experiments in rhesus monkeys, ISCOM-adjuvanted vaccine induced strong proliferative responses of $CD4^+$ cells able to produce both Th1- and Th2-type cytokines (Verschoor et al. 1999).

ISCOMs have been tested in a wide variety of animal species (Barr et al. 1998; Sjolander et al. 1998). In addition, ISCOM-adjuvanted vaccines have been clearly shown to confer protection against infectious challenge in relevant animal models, e.g. against genital infection

with *Chlamydia trachomatis* in mice (Igietseme and Murdin 2000) and HIV-1 in rhesus monkeys (Verschoor et al. 1999). It must also be mentioned that immunization of macaques with ISCOMs containing measles virus HA and fusion proteins induced high titers of neutralizing antibodies even in the presence of maternal antibodies, which, in monkeys receiving conventional attenuated measles vaccine, were able to abrogate the induction of protective antibodies (Van Binnendijk et al. 1997).

The results of the first trials in humans with Iscomatrix-adjuvanted influenza vaccines have been reported recently. In one study, the ISCOM-adjuvanted influenza vaccine induced $CD8^+$ CTL responses in 50–60 percent of participants compared with only 5 percent of those receiving the conventional vaccine (Ennis et al. 1999). In a subsequent study, the adjuvanted vaccine accelerated the appearance of anti-influenza virus antibody response against the three strains present in the vaccine, induced strong antigen-specific proliferative responses, and induced CTL responses in a higher proportion of vaccinees (Rimmelzwaan et al. 2001).

CpG

The immunostimulatory properties of bacterial DNA have been known for some time (see Naked DNA vaccines). However, only relatively recently this property was recognized to be linked to the presence of unmethylated CpG motifs in bacterial DNA, which are absent in vertebrate DNA. CpG motifs are C-G deoxynucleotides linked by a phosphodiester bond, and flanked by appropriate bases, which can vary depending on the animal species in which they will be used (Krieg 2002). The immune modulatory effects of CpG motifs depend on their interaction with the TLR9. Mice lacking the TLR9 do not exhibit the CpG-driven effects (Hemmi et al. 2000). In addition, cells transfected with the murine or human receptor acquire the ability to respond to the more appropriate CpG motifs (Bauer et al. 2001). In humans the expression of TLR9 is highest in those cells that are more consistently directly activated by CpG motifs, such as B cells and DCs (Bauer et al. 2001; Krug et al. 2001). CpG motifs induce strong activation of B cells with production of IL-6 (Yi et al. 1996a); they also increased expression of MHC-II molecules and co-stimulatory molecules such as CD80 and CD86 (Davis et al. 1998), and an overall anti-apoptopic effect associated with increased NFκB activity and c-*myc* expression (Yi et al. 1996b). CpG motifs strongly activate plasmacytoid DCs inducing increased expression of MHC, adhesion, and co-stimulatory molecules, and enhanced ability to produce cytokines such as TNFα, IFN-α, and IL-12 (Hartmann and Weiner 1999; Kadowaki et al. 2001; Krug et al. 2001). The outcome of these activation phenomena will be the polarization of the immune response toward a strong Th1-type functional phenotype. This polarization is so prominent that it also takes place when CpG oligonucleotides are administered in association with other adjuvants, such as aluminum salts, known specifically to induce Th2-type responses, and when they are given neonatally in individuals who are prone to develop Th2-type immune responses (Brazolot Millan et al. 1998). These characteristics are now being exploited for the development of vaccines against cancer and allergies (Krieg 2002). CpG has also been shown to act as a strong mucosal adjuvant (McCluskie et al. 2001).

CpG motifs are now under investigation as vaccine adjuvants in different models, e.g. they have shown optimal adjuvanticity in rhesus monkeys immunized with a heat-killed vaccine candidate against *Leishmania* (Verthelyi et al. 2002) and in orangutans, in which they overcome hyporesponsiveness to an HBV vaccine (Davis et al. 2000). In human phase 1 studies with HBV vaccine, CpG motifs were well tolerated, except for an increased frequency of local pain and flu-like symptoms compared with the currently available vaccine, and induced protective levels of antibodies in 75 percent of vaccinees after the first dose and 100 percent after the second dose (Kenney et al. 2002).

CpG DNA is among the strongest adjuvant systems available to date for the induction of Th1-type immune responses. However, some concerns have been raised about the risk of inducing or reactivating autoimmune phenomena in susceptible individuals, because of their strong immunomodulatory activity mainly at the level of B cells and DCs (Bachmaier et al. 1999; Tsunoda et al. 1999; Miyata et al. 2000) and their ability to activate microglial cells in vitro and in vivo (Dalpke et al. 2002).

Mutants of bacterial toxins as mucosal adjuvants

The ADP-ribosylating toxins LT and CT remain the strongest mucosal adjuvants known so far. Their toxicity, however, seriously limits their use in humans because very limited amounts cause diarrhea in recipients (Levine et al. 1983). These toxins consist of two subunits: the A subunit, which contains the enzymatic activity, and the B subunit, which binds to the G_{M1} ganglioside and other glycolipids. After internalization into the cell, the A subunit of the toxin is proteolytically cleaved, binds to NAD, and transfers the ADP-ribose group to the α subunit of Gs, a GTP-binding protein that regulates the activity of adenylyl cyclase (Holmes 1997). This enzyme becomes permanently activated and causes accumulation of cAMP and secretion of electrolytes and water (Field et al. 1989).

The first approach to develop mucosal adjuvants derived from these toxins, but devoid of their toxic activity, was to use their B subunit (Holmgren et al. 1997). It is now clear, however, that the B subunit alone is a very poor adjuvant. The activity originally reported

was very probably the result of traces of wild-type toxin still contaminating the preparation of the B subunit. The most successful approach to develop nontoxic derivatives of the toxins while still retaining their strong mucosal adjuvanticity has been to produce mutants by site-directed mutagenesis (Freytag and Clements 1999; Rappuoli et al. 1999; Pizza et al. 2001). Some mutations at the active enzymatic site, such as at position 63 in the A subunit (e.g. LTK63 and CTK63 (S → K substitution)), results in total loss of enzymatic activity and toxic properties in vitro and in vivo, even at doses up to 1 mg. Other mutants, such as the LTR72 (in which there is an A → R substitution), retain some residual enzymatic and toxic activity, although at levels several orders of magnitude lower that those observed with the wild-type toxin (Giuliani et al. 1998). Mutants have also been developed to make the toxin resistant to the proteolytic cleavage of the A subunit. The prototype of these mutants, referred to as LTG192 (R → G substitution), however, retains most of the toxic properties of the wild-type parent molecule both in vitro (cytotoxicity on Y1 cells) and in vivo (rabbit ileal loop) (Giannelli et al. 1997).

All these mutants (and others not reported here because of space limitation) behave as strong mucosal adjuvants in mice and other animal models, when co-administered with recombinant proteins, synthetic peptides, and other vaccine constructs, and to favor the development of protective immunity in appropriate challenge models (Pizza et al. 2001). Interestingly, LTK63 and LTR72 mutants also exhibited a strong adjuvanticity when delivered systemically (Jakobsen et al. 2002) and transdermally (Scharton-Kersten et al. 2000). The mucosal adjuvanticity of these mutants was potentiated when the vaccine and the adjuvant were delivered intranasally together with nanoparticles, favoring the uptake of the vaccine at the mucosal level (Baudner et al. 2002). Furthermore, not only did these mutants prime $CD4^+$ T cells; they also primed $CD8^+$ CTLs specific for the co-administered antigen (Simmons et al. 1999), irrespective of the route used for immunization. If CT and CT mutants appear to activate predominantly Th2-type responses (Braun et al. 1999), LT mutants induce more widespread responses, with a preferential induction of Th1-type responses (Takahashi et al. 1996), even in newborn mice that are genetically prone to mount Th2 responses.

From the data available so far, it is clear that the holotoxin structure of the mutants is important for a strong adjuvanticity; indeed, as mentioned above, the B subunit alone is a very poor adjuvant. The enzymatic activity is not necessary itself, because the LTK63 mutant exhibits an important adjuvanticity. A residual enzymatic activity (as in the case of the LTR72 mutant) enhances the adjuvanticity of the molecule in a dose-independent manner.

Clinical experience with these molecules is still limited. The LT or CT B subunits have been extensively tested and shown to be safe after oral delivery together with an inactivated cholera vaccine (Holmgren et al. 1997) and with a vaccine against enterotoxigenic *E. coli* (ETEC) (Hall et al. 2001). The safety of this subunit has also been shown in humans after intranasal immunization (Bergquist et al. 1997). The LTG192 mutant at the level of the protease-sensitive loop has been tested in humans with a whole-cell *Helicobacter pylori* candidate vaccine (Kotloff et al. 2001). In agreement with the animal studies, it caused unwanted effects, such as diarrhea, in about a third of the recipients at doses as small as 25 μg. The LTK63 mutant is now being tested as an intranasal adjuvant in a phase 1 clinical trial together with a subunit influenza vaccine.

SUBUNIT VACCINES

Subunit vaccines consist of one or more antigens, purified from the microorganism or produced by recombinant DNA technology or chemical synthesis, which are able to protect against disease. It is clear that the development of subunit vaccines requires knowledge of the protective antigen(s), the ability to produce and purify them on a large scale, and the ability to prove their protective efficacy in appropriate animal models in vivo and/or in relevant in vitro assays suited to quantify immune responses that correlate with protection. The knowledge of the effector immune response necessary to confer protection in vivo is also very important in order to construct the vaccine with the most suitable formulation (e.g. the most appropriate adjuvant system) and to deliver it via the most effective route. Subunit vaccines against a wide panoply of pathogenic microorganisms are now under development: some are still at the experimental, preclinical stage; others are being tested in clinical trials in humans (at different phase of development); others, finally, have been licensed for human use (Table 2).

The identification of protective antigens is a complex problem, which involves approaches that can differ for viruses, bacteria, and parasites. Viruses have generally small genomes encoding a few proteins, the selection of which for vaccine development is relatively easier than with larger microorganisms. Envelope proteins and glycoproteins are the primary candidates for the induction of neutralizing antibodies, whereas core antigens are usually good candidates for CTL responses. For bacteria and parasites, which have complex genomes, there can be several hundred potential candidate antigens. Therefore, the identification of the potential candidates for the development of subunit vaccines has to be based on a rational approach combining genetic, biochemical, and immunological studies. Until very recently, the starting point was often represented by studies on the pathogenic mechanisms of disease, with the definition of molecules critical in the induction of pathology in the host and/or in the survival of the microorganisms. This approach has been particularly

Table 2 *Status of development of subunit vaccines*[a]

Pathogen	Vaccine construct	Preclinical	Phase of clinical development			Licensure

a) Only purified antigens, recombinant antigens, and conjugated constructs are included. Conventional vaccines (e.g. tetanus and diphtheria toxoids), naked DNA constructs, and synthetic peptides are not included.
b) This vaccine is not commercially available any longer.

successful for those molecules produced only by pathogenic bacteria, such as bacterial toxins and capsular polysaccharides (a few examples follow). However, in several instances the situation may be more complex and the approach to vaccine development may lead to the selection of antigens which, after being tested in animals, are discarded because they do not induce protective responses in humans. The selection then starts again. More recently another way of selecting potentially protective antigens has been applied to vaccine development. Thanks to the progress in computer science and molecular biology, it is now possible to sequence the entire bacterial genome in a short period of time. This permits the comprehensive testing of all the potentially protective antigens in appropriate animal models, and to select vaccine candidates that would not

have been selected based on conventional approaches. Examples of the application of both the conventional and genomic approaches to vaccine development follow.

Past and present: from toxoids and capsular polysaccharides to conjugate vaccines

TOXOIDS AND POLYSACCHARIDES

The first subunit vaccines developed have been the diphtheria and tetanus toxoids (Rappuoli 1997a; Relyveld 1996). As already mentioned at the beginning, the seminal observation leading to the development of these vaccines was that both diseases were caused by a toxin that was produced by the bacterium, and that serum antibodies able to neutralize the toxin were sufficient to protect from disease. The semipurified toxins are inactivated essentially by chemical (formaldehyde) treatment and used as vaccines. For these two vaccines, the titers of serum antitoxin antibodies correlate well with protection. Tetanus and diphtheria toxoids are among the most used vaccines worldwide, because they are part of the pediatric immunizations, which are done within the frame of the Expanded Programme of Immunization of the WHO and Unicef.

In the case of encapsulated bacteria, the choice of the capsular polysaccharide as the antigen of choice for the development of subunit vaccines was based on the observation that mutants without the capsule are nonpathogenic because they are highly sensitive to serum complement. In the case of meningococci, group-specific immunity against disease is mediated by serum antibodies directed against the group-specific capsular polysaccharide (Goldschneider et al. 1969a), through a complement-mediated bactericidal activity (Goldschneider et al. 1969b) and opsonophagocytosis (Vioarsson et al. 1994).

Purified capsular polysaccharides have been used to develop vaccines against MenC, *N. meningitidis* group A (MenA), *N. meningitidis* group Y (MenY), and *N. meningitidis* group MenW135 (MenW135) (Jodar et al. 2002; Morley and Pollard 2002), against 23 serotypes of *S. pneumoniae* (Wuorimaa and Kayhty 2002), against Hib (Ward and Zangwill 1999), and against *Salmonella typhi* using the Vi polysaccharide (Plotkin and Bouveret-Le Cam 1995). All these vaccines have several drawbacks. Capsular polysaccharides are T-independent antigens and they induce transient antibody responses (mostly of IgM and IgG2 isotypes) mainly in individuals aged over 18 years. Their immunogenicity and efficacy are very poor or absent in infants. Furthermore, polysaccharides do not induce immunological memory and repeated immunization not only fails to induce any increase in specific antibody titers, but can also in some cases even induce tolerance in adults (Granoff et al. 1998a). In the case of meningococcal meningitis, polysaccharide vaccines have been proved efficacious in adults and in controlling a MenA epidemic in Africa (Hassan-King et al. 1988). However, the vaccine had limited effects on bacterial colonization and transmission (Hassan-King et al. 1988; Wenger et al. 1997). In the case of pneumococci, the efficacy of the 23-valent polysaccharide vaccine against pneumonia and invasive diseases still remains controversial (Wuorimaa and Kayhty 2002). There is agreement, however, on the fact that this vaccine does not have any effect on carriage rates in children and adults (Dagan et al. 1996).

CONJUGATE VACCINES

The solution to these drawbacks was found by putting together the first and the second subunit vaccines, i.e. the toxoids and the polysaccharides. During the 1920s it was formally demonstrated that the immunogenicity of saccharides was significantly increased when animals were immunized with the sugar covalently linked to a protein, which thus behaved as a carrier molecule (Avery and Goebel 1929). It is now clear that this procedure converts T-independent antigens into T-dependent antigens by providing a source of appropriate T-cell epitopes (present in the carrier protein) that are able to prime carrier-specific T cells; these will provide help to B cells for the production of sugar-specific antibodies. This technology has now been successfully applied to the development of conjugate vaccines replacing simple polysaccharide vaccines. The carrier proteins used in the development of conjugate vaccines are essentially tetanus toxoid, diphtheria toxoid, and the nontoxic mutant of diphtheria toxin, the crossreacting material (CRM) 197 (see below). The only limitation that this technology faces may relate to the overload of carrier protein that patients would receive in the situation where all conjugated vaccines used the same carrier. Indeed, carriers not only help the production of anti-oligosaccharide antibodies, they also induce specific antibodies against themselves. Anti-carrier antibodies present at the moment of immunization with a given conjugate vaccine may suppress the induction of anti-oligosaccharide antibodies. This has been well documented in animals (Barrios et al. 1992), although conflicting observations have been reported so far in humans. Nevertheless, active research is now in progress to select new carrier molecules that would avoid the potential drawbacks of epitope suppression, e.g. synthetic peptides containing selected $CD4^+$ epitopes have been used (Alexander et al. 2000). Alternately, recombinant proteins corresponding to strings of several universal $CD4^+$ T-cell epitopes have been successfully tested as carrier proteins in mice (Falugi et al. 2001).

Hib

The first conjugate vaccine developed has been the vaccine against Hib (Ward and Zangwill 1999). Conjugated Hib vaccines have been shown to be highly

immunogenic and efficacious, and to induce immune memory, Ig isotype switching, and antibody affinity maturation in children aged less than 18 months. All these responses could not be induced after the use of unconjugated polysaccharide vaccine. These vaccines have now been introduced in several countries worldwide (often in association with diphtheria, tetanus, and pertussis vaccines), and their use is being implemented in less developed countries. In the countries where it is used to immunize infants, often starting at the age of 2 months, the conjugated Hib vaccine has contributed to the dramatic reduction in the incidence of invasive Hib diseases (Peltola 2000), e.g. in the USA, from its introduction to 1996, the incidence of Hib invasive disease (i.e. meningitis, sepsis) among children aged less than 5 years had declined by more than 99 percent (Anonymous 1998), a decline that has been maintained also in the following years (Anonymous 2002). It is interesting that among the same pediatric population the incidence of invasive disease caused by nontype b *H. influenzae* remained unchanged (>1 per 100 000 children) since the introduction of the Hib vaccine (Anonymous 2002), suggesting that other serotypes are not overtaking, at least up to now, the ecological niche vacated by Hib. The same dramatic drop of incidence of invasive Hib disease has been reported from several countries (Ward and Zangwill 1999), and more recently from a regional study in Italy (Gallo et al. 2002). Immunization clearly also reduces the carriage of Hib, leading to a reduced transmission of the bacteria to unimmunized patients (Murphy et al. 1993).

Meningococci

The successful approach of conjugate vaccine development against Hib prompted several groups and governmental health authorities to consider the development of a conjugate vaccine against MenC. MenC and MenA vaccines had been already developed and tested favorably in humans for their safety and immunogenicity (Lieberman et al. 1996). However, until very recently the development of a MenA vaccine was almost discontinued by major vaccine companies because of the high prevalence of this group of neisseriae in poor countries, such as those in sub-Saharan Africa (Anonymous 1997), whereas the MenC vaccine was fully developed and finally licensed in several countries. The MenC vaccine, containing as carrier protein the CRM197, was strongly immunogenic (Richmond et al. 2001), and in the UK it exhibited an efficacy of 97 percent among adolescents (15–19 year olds) and 92 percent among toddlers (2–3 year olds) (Ramsay et al. 2001). Longer follow-ups will be required to evaluate whether group C meningococci may be replaced by other strains not contained in the vaccine, as observed with the multivalent pneumococcal vaccine (Eskola et al. 2001), or may undergo C-to-B capsule switching as already documented in neisseriae (Vogel et al. 2000). For the time being, vaccine manufacturers are actively working to develop conjugated vaccines against MenA, MenY, and MenW135 to be incorporated into a tetravalent anti-neisserial vaccine. No major technical problems are foreseen for these vaccines. The real obstacle preventing the development of a definitive anti-neisserial vaccine still remains the problem in producing a vaccine against group B meningococci (MenB) (see below).

Pneumococci

Over the past 16 years, since the first report of a monovalent penumococcal conjugate vaccine (Schneerson et al. 1986), mono-, bi-, tetra-, penta-, hepta-, octa-, nona-, and undecavalent conjugated vaccines against pneumococci have been developed using various carrier proteins, and tested in a large number of clinical trials (Wuorimaa and Kayhty 2002). The conjugate vaccine that has been licensed for human use in Europe and the USA contains polysaccharides from seven serotypes (4, 6B, 9V, 14, 18C, 19F, and 23F) conjugated to the CRM197 as carrier protein. This vaccine has been shown to be safe and highly immunogenic in all age groups (Eskola 2000) and to prime memory responses in early life (Ahman et al. 1998). Importantly, it exhibited 56 percent efficacy in preventing acute otitis media caused by the *S. pneumoniae* strains covered by the vaccine (although protection varied widely among serotypes) (Eskola et al. 2001), and 73 percent efficacy in preventing clinically diagnosed and radiologically confirmed pneumonia in infants (Black et al. 2000). Experiments in mice have recently shown that these vaccines can also be delivered mucosally (intranasally) at birth with nontoxic mutants of LT as mucosal adjuvants and can protect animals against a lethal challenge with pneumococci (Jakobsen et al. 2002), suggesting the possibility of immunizing against these pathogens very early in life by alternate routes.

Other conjugate vaccines

A similar approach is now under consideration for the development of subunit vaccines against other pathogens, e.g. a conjugate vaccine consisting of the capsular polysaccharide Vi of *S. enterica* serovar Typhi conjugated to a nontoxic recombinant *Pseudomonas aeruginosa* exotoxin A, was more than 90 percent efficacious against typhoid fever after two immunizations, 6 weeks apart, in 2- to 5-year-old children in a highly endemic area (Lin et al. 2001). Other conjugate vaccines are under development against various serotypes of group B streptococci using the type-specific capsular polysaccharides (Paoletti et al. 2000; Paoletti and Kasper 2002), and against *Shigella sonnei* and *S. flexneri* 2a using the *O*-specific polysaccharide of LPS

(Cohen et al. 1997; Ashkenazi et al. 1999; Passwell et al. 2001).

Recombinant DNA approach for subunit vaccines

It is not always easy to develop subunit vaccines using molecules directly purified from a given microorganism. In several instances, for many reasons, it is necessary to produce the appropriate antigens by genetic engineering. The issue remains, both for native antigens and for recombinant proteins, of how to select the vaccine candidates. The conventional biotechnological approach to identify microbial components suitable for vaccine development generally starts with the pathogens being cultivated in the laboratory. (This implies that this approach can be very difficult or impossible to apply to microorganisms that *cannot* be grown in the laboratory.) The components of the pathogens are then identified sequentially using biochemical, immunological, and genetic methodologies. The identification of potential vaccine candidates requires the separation of each single microbial constituent. This approach takes time, allows only one protein to be taken into consideration each time, and, importantly, permits the identification of only those antigens that are expressed or can be purified in large quantities. In many cases the most abundant proteins are not the most suitable vaccine candidates, and the genetic tools to identify less abundant candidates may be inadequate or not available. It is also possible that antigens expressed during the infection in vivo are not equally well expressed in vitro during cultivation. This approach can take several years to be successful, and in some cases it can totally fail to identify the relevant vaccine candidates. Once a suitable antigen is identified, most often it is expressed in genetically engineered prokaryotic or eukaryotic vectors, and then purified as a recombinant protein. This conventional approach to vaccine development has been successful in some instances, although it took a long time to provide vaccines against pathogens for which the solution was easy. However, this approach has failed (at least up to now) for those complex pathogens, such as bacteria and parasites, for which obvious major protective antigens were not readily available. Some examples of the successes and the failures of the conventional recombinant DNA approach to the development of subunit vaccines follow.

SUCCESSES IN THE DEVELOPMENT OF SUBUNIT VACCINES

HBV vaccine

The first recombinant subunit vaccine developed was the one against HBV (Valenzuela et al. 1982). This development was particularly fortunate because it was already known that the surface antigen of the virus (the HBsAg) circulated in the bloodstream in large quantities, and that the antibody response to the HBsAg was responsible for protection (Mahoney and Kane 1999). The yeast- and mammalian cell-derived vaccine has replaced the first-generation, plasma-derived vaccine. This vaccine is highly effective: it induces seroprotective levels of antibodies (i.e. >10 mIU/ml) in >95 percent of individuals and prevents the development of chronic hepatitis in at least 75 percent of immunized infants born to hepatitis Be antigen (HBeAg)-positive mothers (Poovorawan et al. 1992). This vaccine has now been incorporated into the routine infant or adolescent immunization programs of 129 countries worldwide (Van Damme and Vorsters 2002). In addition to preventing both acute and chronic diseases, mass immunization against HBV has clearly reduced the incidence of hepatocellular carcinoma in children from Taiwan, where it dropped from 0.70/100 000 children in 1981–86 to 0.57 in 1986–90, and further to 0.36 in 1991–94 (Chang et al. 1997, 2000). The HBV vaccine can therefore be considered as the first successful anti-cancer vaccine.

Recent work is now concentrated on improving the efficacy of this vaccine by, for example, using novel adjuvants such as MF59 (Heineman et al. 1999), the AS04 (MPL + aluminum hydroxide) adjuvant system (Desombere et al. 2002), or the CpG oligonucleotides (Davis et al. 2000). The final objective of this work is to reduce the number of nonresponders to the currently available vaccine, and to attempt the development of a therapeutic vaccine for individuals with chronic hepatitis using either available recombinant vaccines or synthetic constructs containing selected HBcAg CTL epitopes (Engler et al. 2001).

Acellular vaccine against pertussis

A genetically detoxified pertussis toxin was the first bacterial recombinant subunit vaccine developed (Rappuoli 1997b; Del Giudice et al. 1998). Instead of preparing toxoids through chemical treatment, as in the case of diphtheria and tetanus toxins, the approach consisted of knocking out the enzymatic (toxic) activity of the pertussis toxin by substituting in the S1 subunit of the amino acids that were critical for enzymatic activity. The mutant at the level of amino acid positions 2 and 179 (Pizza et al. 1989) was further characterized and associated with other *Bordetella pertussis* antigens such as filamentous HA (FHA) and pertactin for the development of an acellular pertussis vaccine (Rappuoli 1997b; Del Giudice et al. 1998). The vaccine containing the genetically detoxified toxin was shown to be safe and efficacious in various trials. It is interesting that, 5–6 years after the primary immunization schedule, this vaccine still exhibited an efficacy of about 80 percent (Salmaso et al. 2001).

The genetic detoxification of ADP-ribosylating toxins was then extended to LT and CT to develop safe and

effective mucosal adjuvants. These molecules have already been discussed above. The genetic detoxification will now also be possible for the anthrax toxin, after the elucidation of its fine structure (Lacy and Collier 2002), for the development of a new generation of safer and more effective anthrax vaccines.

Lyme disease

The search for antigens suitable for the development of protective vaccines against Lyme disease, a tick-borne bacterial infection caused by *Borrelia burgdorferi*, has essentially concentrated on outer surface proteins (Osp). In preclinical studies, the recombinant OspA, OspB, and OspC gave the best levels of protection against infectious challenge (Fikrig et al. 1992). The vaccine developed consisted, however, of one single recombinant – lipidated protein, OspA – which in 1999 was recommended for use in 15- to 70-year-old people living or visiting areas at risk of tick bites (ACIP 1999). In large human trials, this vaccine exhibited an overall efficacy of 80–90 percent after three doses of vaccine (Sigal et al. 1998; Steere et al. 1998). As OspA is expressed by *B. burgdorferi* when it develops in the tick, protection conferred by this vaccine is mediated by a transmission-blocking immunity, through anti-OspA antibodies that are able to destroy and eliminate the spirochetes in the midgut of the ticks (De Silva et al. 1996).

Based on observations made in mice (Feng et al. 1995), some concerns were raised on the risk that Lyme arthritis could be induced by OspA-based vaccines. Human DRB1*0401-positive synovial fluid T cells can respond to OspA; this is most probably the result of the recognition of the OspA amino acid sequence 165–173 which is homologous to a sequence present within the α_L chain of human LFA-1 (amino acids 332–340) (Gross et al. 1998). It is not clear yet whether this vaccine can really induce Lyme arthritis via antigenic mimicry, at least in susceptible individuals. A recent comprehensive post-licensure study on serious adverse events after the administration of over 1.4 million doses of the Lyme disease vaccine did not detect unexpected or unusual patterns. Importantly, the number of reported arthritis-related events were much lower than those expected by the safety data reported in the efficacy trial (Lathrop et al. 2002).

FAILURES IN THE DEVELOPMENT OF SUBUNIT VACCINES

Among the examples of failures of the conventional approach to development of subunit vaccines are three diseases, which account for a heavy burden of morbidity and mortality: AIDS, tuberculosis, and malaria. In these three cases, the complexity of the pathogens, the effector immune mechanisms to be induced, and the systems required for this induction are such that multifaceted approaches are required in order to achieve adequate protective efficacy.

In the case of AIDS, the conventional approaches to vaccine development have essentially focused onto the proteins of the HIV-1 envelope, mainly the gp120, facing the serious problem of antigen variability and, as a consequence, the poor ability of these vaccine constructs to induce antibodies that are able also to neutralize heterologous viral strains. More recent approaches are based on the selection of more conserved antigen candidates, such as regulatory proteins of HIV-1 (see below). On the other hand, observations coming from both experimentally infected animals and naturally infected individuals strongly suggest a central role for CTLs, together with antibodies, in conferring sustained immunity against HIV-1. This has implied the development of a panoply of approaches aimed at inducing both antibody and CTL responses through the use of various delivery systems for both DNA and protein constructs. Many of these constructs have been tested, or are being tested in phase 1 and 2 clinical trials. One of them is in phase 3 (efficacy) trial. All these 'trials and tribulations' in the field of HIV-1 vaccines have been extensively reviewed in the past few years in excellent reviews (Johnston and Flores 2001; Weiss 2001; Graham 2002; Letvin et al. 2002; Lifson and Martin 2002; McMichael and Hanke 2002).

A live-attenuated vaccine against tuberculosis (the so-called bacillus Calmette–Guérin (BCG)) has been available for more than 70 years. Despite the fact that it is one of the most used vaccines in the world, its efficacy remains controversial, e.g. it protects infants against disseminated tuberculosis, but not adults against the pulmonary disease (Fine 1995). In consideration of the increasing burden of this disease, the development of new efficacious vaccines against tuberculosis is highly desirable. Several factors, however, limit its development, including the intracellular location of *Mycobacterium tuberculosis*, which leads to the need for the development of Th1-type and MHC class I-restricted CTL responses for efficacious clearance of the bacteria. A further problem is the lack of ideal experimental animal models of infection. Surface antigens, such as the antigen 85, hsp60, ESAT-6, etc. have been tested in the preclinical setting, mainly in the form of DNA vaccines, but also as recombinant antigens. However, most of the approaches rely on the development of viable mycobacterial vaccines and on mixed approaches (Ridzon and Hannan 1999; Kaufmann 2000, 2001).

The situation is even more complex for malaria, the burden of which is increasing as a result of drug resistance and worsening of environmental and social conditions, mainly in Africa (Greenwood and Mutabingwa 2002). Immunity against malaria parasites is not only species specific (thus requiring specific constructs for *P. falciparum*, *P. vivax*, *P. malariae*, and *P. ovale*), but also specific for each stage of development. In addition,

antigenic variability has been widely described in malaria parasites. Antigens specific for the pre-erythrocytic forms (sporozoites and liver stages), several antigens of asexual forms, and other sexual forms of the parasites have been characterized and produced under different forms by recombinant DNA technology. Furthermore, the effector mechanisms required for protection are different for pre-erythrocytic vaccines (Th1-type, CTLs) and for erythrocytic (both sexual and asexual) vaccines (mainly, but not exclusively, antibodies). Some of the recombinant antigens have also been tested in still nonideal animal models (primates) and some also in humans, as in the case of the circumsporozoite protein fused to the HBsAg particle (referred to as RTS,S) and formulated with the so-called AS02 adjuvant system (MPL + QS-21 (Stoute et al. 1997; Bojang et al. 2001; see also above)). Despite the low levels of transient protection reported, these constructs must be considered as first-generation candidates that still need optimization for their application in malaria-endemic areas (Good 2001; Richie and Saul 2002). It is likely that an ideal malaria vaccine in the future will consist of a mixture of antigens from the different stages of development of the parasite.

There is hope that the comprehensive genomic approach will provide the solution in the selection of the most appropriate antigens in the development of effective vaccines against malaria and tuberculosis.

Genomics applied to vaccine development

The possibility of access to the whole genome sequences of microorganisms, even the most complex, has entirely changed the perspectives and ways of thinking in the process toward vaccine development. By completely reverting the conventional approach (hence the definition of 'reverse vaccinology' coined by one of us (R.R.) (Rappuoli 2000)), the genomic approach does not start from microbiology, but from the comprehensive genomic sequence of the pathogen and, by strict computer analysis, it can predict those antigens that are most likely to be vaccine candidates. One of the novelties of this approach is that cultivation of the pathogen is not required. This avoids handling of dangerous pathogens and also offers the possibility to conceive the development of vaccines for pathogens that cannot be cultured. In addition, the analysis of the potential vaccine candidates takes into consideration virtually all the proteins of the microorganism, irrespective of whether they are expressed in vitro and/or in vivo, the abundance of the protein, whether it is immunogenic in vivo during natural infection, etc. In this respect, this approach is totally unbiased, because all proteins are equally screened as potential vaccine candidates. The feasibility of the genomic approach relies heavily on the availability of a high-throughput system allowing the screening for the development of protective immunity of a very large number of potential candidates reproducibly and in a relatively short period of time. The availability of good animal models of infection and protection, and the availability of immunological correlates of protection, can enormously help the identification of good vaccine candidates. Unfortunately, good correlates of protection are rarely available and this limits the effectiveness of the approach, e.g. despite the fact that the genome of *Helicobacter pylori* has been available for a few years, the development of a vaccine against *H. pylori* has been based up to now essentially on the conventional approaches detailed above (Del Giudice et al. 2001a, b). The other limit of the genomic approach is inherent to molecular biology, and refers to its inability to identify nonprotein antigens, such as polysaccharides, which are components of successful vaccines (see above), and to identify CD1-restricted antigens such as glycolipids, which represent new promising vaccine candidates, as in the case of tuberculosis (Schaible and Kaufmann 2000).

THE GENOMIC APPROACH TO BACTERIAL VACCINES

Group B meningococci. The first bacterial pathogen to be tackled using the genomic approach was the MenB, for which all the conventional approaches used so far have consistently failed. This is even more dramatic because MenB still remains the most prevalent cause of meningococcal meningitis in a very large portion of the world (Rosenstein et al. 2001).

Unlike MenC, for which a conjugate vaccine now exists and for MenA, MenW135, and MenY, for which conjugate vaccines are under development, the use of capsular polysaccharide as the basis of a vaccine against MenB is highly problematic. The MenB capsular polysaccharide is identical to a carbohydrate ($\alpha(2\rightarrow8)$*N*-acetyl neuraminic acid or polysialic acid), which is widely expressed by human cells, e.g. neural cells during ontogenesis (Finne et al. 1987). This renders this structure very poorly immunogenic (Zollinger et al. 1997). Moreover, the administration of this polysaccharide as a conjugate may elicit antibodies crossreacting against the self-antigen (Hayrinen et al. 1995; Granoff et al. 1998b).

Another approach to vaccine development against MenB is based on surface-exposed proteins contained in outer membrane vesicles (OMV). These vesicles contain the major porin proteins, other proteins of molecular masses between 60 and 100 kDa, and LPS. In different efficacy trials, OMV-based MenB vaccines have been shown to elicit serum bactericidal antibody responses and to protect against the development of meningococcal disease (Bjune et al. 1991; de Moraes et al. 1992; Boslego et al. 1995; Tappero et al. 1999). On the one hand, these trials demonstrated that the development of efficacious vaccines against MenB was feasible, but, on the other, they clearly showed the intrinsic limitations of

the OMV-based approach, mainly as a result of the high degree of sequence and antigenic variability of the major proteins that they contain (mainly class 1 porin protein, PorA). Indeed, OMV vaccines induced protective (bactericidal) antibodies at all ages only against the homologous strain of bacteria; they failed, however, to induce protection against heterologous strains, mainly among the youngest children (Tappero et al. 1999), i.e. those more susceptible to meningococcal diseases. To enhance the number of potential strains covered by the vaccine, OMVs were prepared from two strains, each expressing three different PorA proteins. This hexavalent PorA vaccine exhibited poor activity in infants in which a fourth dose was required to induce substantial bactericidal antibody titers (Cartwright et al. 1999). Furthermore, as a result of the extremely high variability of the PorA proteins, such a vaccine would have the potential to cover less than 50 percent of the circulating MenB strains (Tondella et al. 2000), without considering the risk of antigenic drift or the emergence of pathogenic PorA-negative strains.

The attempts to develop noncapsular, non-OMV vaccines using potentially conserved proteins have also failed so far. The proteins that have mostly been investigated are either variable at the level of amino acid sequence, such as the transferrin-binding protein B (TbpB) (Rokbi et al. 2000), or expressed by only about 50 percent of the MenB strains circulating, such as the neisserial surface protein A (NspA) (Moe et al. 1999).

To identify novel potential vaccine candidates able to induce protective immunity against all MenB strains, the genomic approach was applied by sequencing and deciphering the entire genome of the virulent strain MC58 (Tettelin et al. 2000). While the work of nucleotide sequencing was still in progress, unassembled DNA fragments were investigated to identify open reading frames that potentially coded for novel surface-exposed or exported proteins. Computer analysis predicted more than 600 novel antigens, 350 of which were successfully expressed in prokaryotic cells, purified and used to immunize mice. The immune sera were then tested to confirm to surface location of the antigens by fluorescence activated cell sorter (FACS) analysis and to evaluate the presence of antibodies with bactericidal activity against a broad range of MenB strains, the titers of which are known to correlate with protective immunity against meningococci. Of the 85 novel surface-exposed antigens, 25 identified induced bactericidal antibodies at titers, for some of these antigens, similar to those induced by efficacious OMV vaccines. By analyzing in detail the nucleotide and amino acid sequences in large numbers of strains, it was evident that most of these newly described antigens were very well conserved in strains representative of the circulating meningococcal population, thus suggesting the potential of their use to induce protective immunity against a broad range of strains (Pizza et al. 2000). Some of these conserved antigens that could induce bactericidal antibodies in mice against large panel of MenB strains are now being developed for testing in phase 1 trials in humans.

The information derived from the genome is also being exploited to identify those bacterial antigens that are selectively expressed in vivo at the moment of interaction with the endothelial cells. Using DNA microarrays of MenB it has been shown that the contact of the bacterium with the cell induces upregulation of 189 genes, 40 percent of which are located at the bacterial surface. Five of these surface antigens, not originally retained by the first screening of potential candidates, induce bactericidal antibodies in mice and may represent additional promising vaccine candidates against MenB (Grifantini et al. 2002).

Other bacteria

The genomic, reverse vaccinology approach is now being exploited for the identification of vaccine candidates for the development of vaccines against tuberculosis (Cole et al. 1998), syphilis (Norris and Weinstock 2000), group B streptococci (Tettelin et al. 2002), pneumococci (Wizemann et al. 2001), *Chlamydia pneumoniae* (Montigiani et al. 2002), and others. The entire genomes of many bacteria have been published or are going to be published. The reader is referred to the website www.tigr.org for detailed and fast-growing information. Again, the availability of high-throughput screening systems will enormously help in accelerating the selection of vaccine candidates to move from experimental laboratory models to clinical testing.

THE GENOMIC APPROACH TO PARASITE VACCINES

The attempts made to develop a vaccine against malaria have already been mentioned above. Despite the preliminary results obtained in the field with a recombinant pre-erythrocytic vaccine construct given with a particular adjuvant system (see above), there is still a long way to go before the successful development of an efficacious vaccine able to combat this disease. Malaria, together with AIDS and tuberculosis, remains one of the most dangerous diseases threatening human health. The increase of resistance to anti-malarial drugs and anti-vector insecticides makes the development of an efficacious vaccine of paramount priority. A panoply of plasmodial antigens has been identified as potential vaccine candidates; some have been tested in clinical trials in humans, but none has so far provided the desired breakthrough (Richie and Saul 2002). The final solution may derive from the genomic approach. Of the 14 chromosomes of *P. falciparum*, two have been fully sequenced (Gardner et al. 1998; Bowman et al. 1999), whereas the annotation for others is in progress (website www.tigr.org). The analysis of the whole genome will show which genes are expressed by the parasite at its

different developmental stages (sporozoite, live stages, and asexual and sexual erythrocytic stages). Expression of genes predicted to be immunogenic as recombinant proteins or as DNA vaccines will eventually provide the effective vaccine against malaria. The task is not easy, because malaria species that infect humans can infect only particular monkey species, thus limiting the possibilities of high-throughput screening of the candidate antigens, and requiring more and more clinical trials with new candidate vaccine constructs. However, it is encouraging that in recent years there has been an increasing involvement of governments and nonprofit foundations, which has significantly increased the amount of funds allocated for malaria vaccine research and development (Nossal 2000).

Active work is now in progress toward the sequencing of the genome of the other human malaria parasite, *P. vivax*, trypanosomes, *Schistosoma mansoni*, *Brugia malayi*, and other parasites (website www.tigr.org).

THE GENOMIC APPROACH TO VIRAL VACCINES

Despite their small size and the fact that viral genomes have been available for a long time, the information derived from the genomic approach has been poorly exploited for vaccine development. The best example, and also the first, of reverse vaccinology applied to virus discovery and the development of vaccines against viral infections is given by the HCV. The virus cannot be cultured and it has never been observed by electron microscopy. Identification of the etiological agent was only possible through cloning and sequencing of the HCV genome (Choo et al. 1989), which allowed the prediction of the envelope proteins; these were then shown to induce protective immune responses in chimpanzees (Choo et al. 1994).

Until very recently, most of the attention has been focused on proteins from the viral particle, such as those of the envelope and the core of the virus particle. The best example is provided by the long-term efforts to develop HIV-1 vaccines based on different forms of the major envelope protein gp120 and/or on the other structural proteins encoded by the *gag* gene. It is now evident that other proteins, which are expressed in too limited amounts to be purified from the virus or which are not structural proteins (e.g. Tat, Nef, Rev, and Pol), can be protective in relevant experimental animal models and may be exploited for the development of vaccines in humans (Cafaro et al. 1999, 2001; Osterhaus et al. 1999; Pauza et al. 2000; Ensoli and Cafaro 2002). The promising results obtained so far with these 'unusual' antigens strongly suggest that we have to change our way of thinking about the way of inducing protective immune responses and to consider that even nonstructural, nonexposed proteins, and even naturally poorly immunogenic antigens, can represent potential candidate vaccines when they are correctly expressed and appropriately delivered to the host, e.g. it has been shown that the HIV-1 Tat protein is able to target to DCs and to favor their maturation and function, thereby enhancing antigen-specific T-cell responses (Fanales-Belasio et al. 2002), a finding totally unexpected based on the information available from the conventional approaches to vaccine development.

ACKNOWLEDGMENTS

We thank Derek O'Hagan and Maria Lattanzi for the supervision of Tables 1 and 2, respectively, Paolo Ruggiero and Samuele Peppoloni for critical reading of the manuscript, and Catherine Mallia and Fabiola Lai for superb secretarial assistance.

INTRODUCTION

The purpose of this chapter is to introduce the use of mathematical models in the design of vaccination programs. Like any other healthcare interventions, the aim is to reduce disease, and the success of the program can be measured in terms of the amount of disease prevented, i.e. a quantity. Whenever a problem can be expressed in quantitative terms (i.e. numbers), it lends itself to mathematical formulation, and a whole host of techniques can be used to help solve it. Many people have an aversion to mathematics, but this should not prevent its use when its use is clearly indicated. In this context mathematics is acting as a supporting subject. Just as the development of diagnostics often requires support and insight from chemistry, so the control of infectious disease can make use of mathematics. However, we are not attempting to produce a manual for mathematical models, or indeed convert those with an aversion to equations; rather we seek to explain the content of models and the conclusions that flow from them.

Models (mathematical or otherwise) are conceptual simplifications of complex biological problems. As such, they are always open to the criticism that some relevant and important process or factor is missing. The adage that 'all models are wrong, but some are useful' is true. The decisions taken about which processes are to be included (and which are to be omitted) are critical to determining the usefulness of a model. This is true of mathematical models of problems in other subjects, e.g. engineering. It is clear that judicious use of mathematics can make bridges safer, even when many of the potential complexities cannot be modeled. The definitive test is always when the bridge is actually built and, indeed, there are good examples of bridges failing when the models clearly missed out important processes. However, the next time you are passing over a bridge, it is of some comfort to think that somebody has performed some calculations to demonstrate that it can take your weight.

The principal reason for using mathematical models in the design of vaccination programs is that appropriate experiments are impossible, usually on logistic grounds. If somebody develops a vaccine that they believe induces a protective immune response, there is an agreed route through which they can demonstrate efficacy and safety. It might then be suggested that this vaccine, if given to 75 percent of the population, will prevent 1 500 deaths per year. The only way of demonstrating the potential impact of the vaccine at the population level without actually introducing the program is to model it, i.e. use quantitative frameworks to predict the potential outcome. Note that this is true of the majority of public health interventions – designating 'treatment' and 'control' populations is usually not possible. Clearly, to predict the impact of a vaccine even reasonably accurately requires that we can initially predict the outcome of infection without any intervention.

Just as mathematics has become a mainstay of engineering, so mathematical or quantitative descriptions of pathogen transmission dynamics are increasingly used to support decision-making in design of control programs against infectious disease. Our emphasis in this chapter

is on the insights that modeling provides and in what ways these might be instructive in vaccine program design. This chapter concentrates on vaccination, and the central questions of vaccination program design is: 'Who should be vaccinated, what with, and when?'

These are nontrivial questions, and the literature addressing them is substantial and growing. An introduction is given by Anderson and May (1991), which provides a (rather technical) base for more recent advances. More accessible reviews include Nokes and Anderson (1988) and Fine (1993). Consequently, in this chapter, we concentrate on the situation for which the results are best-established: viruses with single serotypes, where immunity after infection is long lasting. The classic examples (archetypal viruses) are measles, mumps, and rubella (MMR). It is no coincidence that this is the simplest circumstance – a consensus on the population biology and epidemiology of more complicated infections is yet to be found.

BASIC CONCEPTS

In this section, we introduce the central idea of infectious disease epidemiology: it is a dynamic process driven proximately by the rate of infection and, ultimately, the availability of people to be infected.

Individual vs population

The population level patterns (epidemiology) of infectious disease are very different from noninfectious disease. An infected individual acts as a potential source of infection to others in a population – an individual with a noninfectious condition poses no such risk. With infectious disease there is a necessary relationship between the *incidence* and *prevalence*: if the prevalence of infection is zero, then there is no possibility of incidence being anything other than zero (Figure 1), i.e. if nobody is infected with smallpox, nobody can become infected with smallpox. This is not the case for noninfectious or noncommunicable disease, where the individual risk of developing the disease is little influenced by the amount of disease in the population.

It follows from this simple observation that infectious disease has to be studied at a population or community level if it is to be controlled. The risk of disease to an individual depends on the health (infection) status of all the other individuals with whom they come into contact. Likewise, an intervention that acts on an individual will have consequences for everybody else in the population. If you successfully vaccinate 20 percent of a population, the remaining 80 percent who were unvaccinated will still receive some protection from infection because they have fewer people from whom to acquire infection.

An important distinction must be drawn between infection and disease. Infected individuals are not guaranteed to develop disease and, for most pathogens, most infections are relatively asymptomatic. However, an individual infected with influenza but without clinical symptoms can transmit the virus to another individual who subsequently dies. It follows that control of infectious disease at the population level requires that it is infection that is considered rather than disease. Unfortunately, most data available are highly biased towards cases of clinical disease, and uncomplicated infection is usually unobserved unless special effort is made.

Transmission dynamics and susceptibility

It is also clear that incidence is dependent on susceptibility to infection: if there are no susceptible individuals to infect, the incidence is, again, necessarily zero. If it were possible to make everybody immune to measles tomorrow, nobody would become infected. This relationship between prevalence and incidence gives an inherent nonlinearity in patterns of infectious disease. Under simple assumptions of random transmission (see below), we can write the incidence of infection as the product of three numbers. Suppose that individuals in a population contact each other at some rate, c, and there are X susceptible and Y infected individuals, making a total population size of N ($=X + Y$). Then the rate at which each susceptible contacts an infected individual is:

$$c\frac{Y}{N} \qquad (1)$$

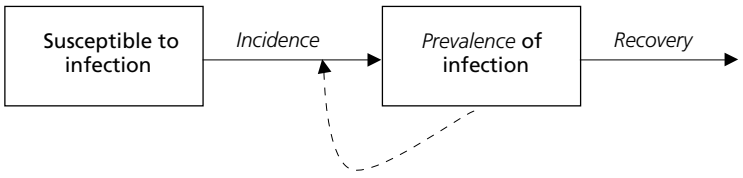

Figure 1 *Relationship between incidence and prevalence for an infectious disease. The boxes represent two sorts of individuals: those who might be infected (i.e. are susceptible to infection) and those who are infected. The prevalence of infection is the number of individuals currently infected, and is expressed as a proportion or percentage. The solid arrows represent time-dependent rates of movement of individuals. Incidence is a measure of the rate at which individuals become infected, and is often expressed as a proportion of the population per unit time (the attack rate). Recovery from infection can generally be the result of immunological clearance of infection or death of the infected individual. The dotted line represents the dependence of incidence on prevalence.*

For example, suppose that the contact rate is 10 individuals per week, and half of the population is infected, then the average susceptible will contact 5 infected people per week. Now suppose that on each contact between a susceptible and infected individual there is a probability, p, that transmission occurs (i.e. the susceptible becomes infected). Consequently, the rate of infection per susceptible is:

$$pc\frac{Y}{N} \tag{2}$$

This quantity is also known as the 'force of infection'. Continuing our numerical example, if the probability of transmission is 0.1, the rate of infection per susceptible is 0.5 per week. This can be translated into an average time before infection of 1/0.5 = 2 weeks. The unsurprising result is that the more infected individuals there are in a population, the more likely that each susceptible becomes infected, and the faster they become infected.

The total rate of infection in the population (i.e. taking into account all the susceptibles) is the incidence (e.g. the number of cases of infection per week):

$$pc\frac{Y}{N}X = \frac{pcY(N-Y)}{N} \tag{3}$$

This relationship is drawn in Figure 2. The implicit assumption for this simple example is that individuals are either susceptible or infected. Lack of either susceptible or infected individuals reduces incidence. Incidence is greatest when there is a plentiful supply of both. This nonlinear relationship between incidence and susceptibles and infecteds is what creates 'transmission dynamics'. During an epidemic, the number of infected individuals starts small, but a positive incidence means that infection increases, increasing incidence further, and so on. Eventually, the numbers of susceptibles will be depleted, and incidence will start to fall. Thus, changes in incidence at any point in time have important consequences in the future, making prediction of the dynamic (through time) changes intrinsically complicated.

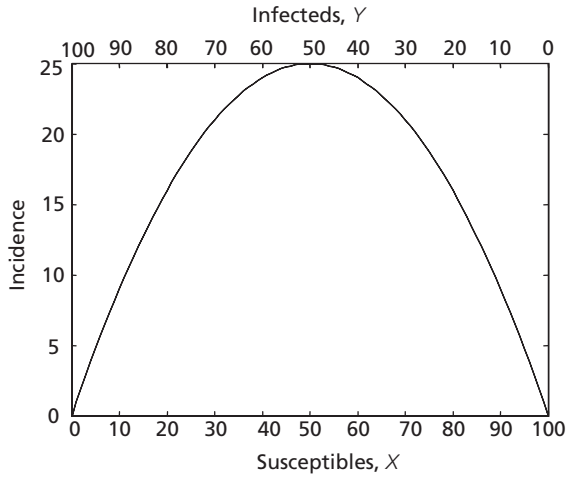

Figure 2 *The relationship between incidence (number of new cases per unit time), and the numbers of susceptibles in a population of 100 individuals. The incidence is zero when either there is nobody to infect (X = 0, Y = 100) or there are no infectious individuals (X = 100, Y = 0). See text (Equation 3).*

The simplest dynamic model

The preceding section makes it clear that there are intimate links between rates of infection, prevalence of infection, and proportion susceptible. To understand these links and the dynamic consequence of changing any of these quantities (e.g. reducing susceptibility by vaccinating), it is necessary to consider them together in a single model framework. Mathematics provides the tools to do this.

Imagine a closed population such as the passengers and crew on a cruise liner, i.e. a population in which birth, death, immigration, and emigration do not usually occur. This implies that we are thinking of a relatively short time period. Let us consider the simplest situation (i.e. the MMR paradigm). We can divide the population into three mutually exclusive groups or classes: susceptible, infected (and infectious), and recovered (and immune).

In this case, the only process occurring as far as the susceptible population is concerned is infection, which occurs at a rate given in Equation 3. The number of infected individuals is being increased by infection (at the same rate as susceptibles are lost), but also decreased by recovery. The immune population is increased in the same manner, i.e. as each person recovers and leaves the infected class, he or she enters the immune class. We can tie these processes together by considering the rate at which the populations are changing. Figure 3 sketches a 'flow diagram' indicating the three classes of individual and the rates of flow between them.

As before, we define X and Y to be the numbers susceptible and infected respectively, and introduce Z as the numbers immune. We can then say that the rate of change of X is written as dX/dt. This quantity has units of 'people per unit time': if it is zero, the susceptible population is not changing; if it is greater than zero the susceptible population is increasing; if it is less than zero (negative) the susceptible population is decreasing. Taking all the assumptions together, the equations for this simplest model are:

$$\frac{dX}{dt} = -pc\frac{Y}{N}X \tag{4}$$

$$\frac{dY}{dt} = +pc\frac{Y}{N}X - \frac{1}{D}Y \tag{5}$$

$$\frac{dZ}{dt} = \frac{1}{D}Y \tag{6}$$

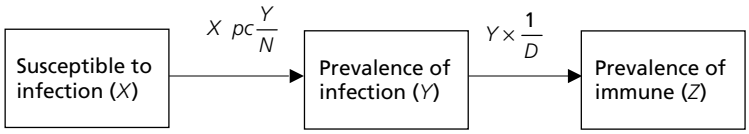

Figure 3 *A flow diagram for the simplest possible model of a microparasitic infection that produces a solid, life-long immunity (e.g. mumps, measles, and rubella or MMR). In comparison with Figure 1, we have now introduced an explicit immune class of individuals, and added variables (*X, Y, *and* Z*), which are the numbers of individuals within each class. The total population is* N = X + Y + Z*. Each individual in the population falls into one, and only one, class. The arrows between the classes represent the flow of individuals, and the rate of flow is given as an equation. See text (Equations 4–6).*

The incidence rates are as previously (see Equation 3). The recovery rate is written as $1/D$ where D is the duration of infection. Note that the parameter c is a rate and D is a duration, and must be expressed in the same time units, i.e. it is wrong to include c as five contacts per week and D as a duration of 14 days. The only other information necessary to solve these equations is the 'initial conditions', i.e. the numbers in each class at the start.

We are not going to enter into a mathematical discussion of these equations, but rather simply state that they are easily solved in many computer packages. Figure 4 gives an example of such a solution. The epidemic is shown as the bold line, reaching a peak prevalence of 40 people in 100 infected after 4 weeks. The susceptible population falls continuously, although note that a small proportion of people escape infection. The immune population (dashed line) rises throughout as people pass from susceptible through infected and recover.

One thing that should be clear from this model is that the shape of the epidemic is determined by both the availability of infection and the susceptibility. The reason that everybody does not become infected on the first day is that infection is rare, but the prevalence of infection increases because the rate of infection is greater than the rate of recovery. The reason that infection prevalence falls after 4 weeks is that only about 30 people are susceptible, so the rate of recovery is greater than the rate of infection.

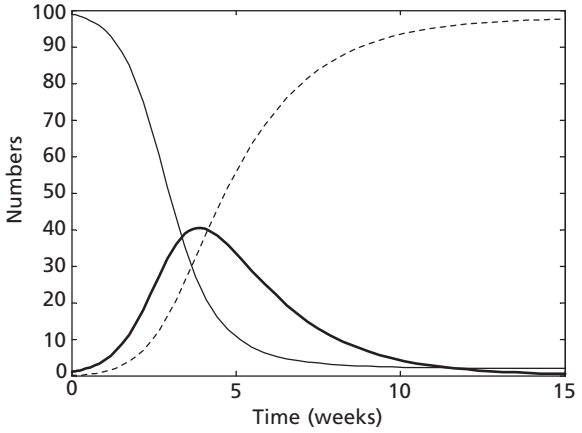

Figure 4 *An example outcome from the simplest model (see text, Equations 4–6). The lines show the numbers in each class: susceptible (*X*), infectious (*Y*, bold) and immune (*Z*, dashed). The parameters are:* c *= 20 per week,* p *= 0.1, and* D *= 2 weeks. The initial conditions are* X *= 99,* Y *= 1, and* Z *= 0.*

Statistical and political complications

Generally, for infectious disease studies, individuals cannot be considered as statistically independent observations. For infectious disease, the incidence is a (nonlinear, complex) function of the prevalence. Noninfectious disease epidemiology is essentially a statistical study of the relationship between risks and disease where individuals can be treated as heterogeneous, but independent, replicates. This makes observational research into infectious disease more difficult and, to some extent, the appropriate methods are still under development (e.g. see Becker 1989).

Infectious disease also introduces conflicts between populations and individuals, because of the interdependence. Some of these conflicts are discussed in Medley (1996), but a couple of examples will demonstrate. No vaccine is completely free from risk of adverse reactions, so each parent would like their children to avoid both infection and vaccine. This is possible only if all other parents have their children vaccinated, i.e. everybody would like everybody else to use the vaccine, because then they would not have to (see also Nokes and Anderson 1988, 1991).

Another conflict arises if chemotherapy is available to prolong the infectious life of infected individuals. Clearly, such a therapy is advantageous to the individual, but will almost certainly increase the total number of people infected, which is disadvantageous to the population (e.g. Anderson et al. 1991). These conflicts are occasionally seen when those responsible for the health of populations (e.g. government departments) enforce control measures that are apparently detrimental to individuals. A conflict arises because the best policy depends on the perspective taken: what is best for an individual might not be the best for the population, and vice versa.

PROCESSES OF INFECTIOUS DISEASE EPIDEMIOLOGY

Having introduced the basic concepts, in this section we go through the processes that drive infectious disease

epidemiology, and hence form the components of mathematical descriptions of infectious disease dynamics.

Routes of transmission

Pathogens must be passed from one individual to another if they are going to survive, even if only because no host is immortal. From an evolutionary point of view, the pathogen that transmits the most is the most successful (the 'fittest'), and will out-compete the less transmissible. From an epidemiological viewpoint, if the transmission dynamics of infection, and hence the impact of vaccination, are to be predicted, a critical knowledge is how many and which individuals are infected by an infectious case.

Transmission can be classified in a number of ways. In Table 1 we give a classification system based on three criteria. First, infections can be considered in terms of their ultimate source: other people, other animal species (zoonotic), or the environment. Second, within each of these categories, the route of transmission essentially defines who is likely to be exposed, e.g. an infection that can use the maternal route will potentially infect children; a sexually transmitted pathogen will potentially infect sexual partners, etc. Vectors can transmit both human and zoonotic pathogens. Third, the mode of infection essentially defines the physical manner in which the pathogen transfers from one individual to another, so that children can be infected maternally via a number of modes (e.g. across the placenta or via breast milk). Thus, knowing the route of transmission helps define the at-risk contacts of an infected individual, and knowing the mode of transmission helps define control strategies to reduce the risk of those individuals. Distinction should also be made between transmission modes that are contaminative (i.e. there is no multiplication of the pathogen) and reservoir; multiplication of malaria within the vector reservoir is different from the contamination of shared drug-injecting equipment with HIV.

Quantification of transmission probability

Contact between an infectious and a susceptible individual does not guarantee transmission. To estimate a probability of transmission given a contact, the contacts have to be defined and countable. This is not straightforward, e.g. for sexually transmitted infections (STI) there is the possibility of measuring the contact rates and transmission probability in terms of both sexual partnerships and sexual acts (within a partnership) (see Blower and Boe 1993).

Suppose that we are interested in transmission of HIV from intravenous drug-using women. There are three routes through which infection can pass, and hence three groups who might be infected: children, equipment-sharing partners, and sexual partners. Suppose that these women have, on average, one child every 4 years; then the contact rate, c_1, for this route is 0.25 different children per year. Likewise we can define c_2 as the average number of different injecting partners per year,

Table 1 *Classification of transmission*

Source	Route	Mode	Examples (organism)
Human	Maternal	Transplacental	*Toxoplasma gondii*, rubella, CMV, *Treponema pallidum*
		Transmammary	HIV, CMV
	Environmental contamination	Food borne	HAV, *Vibrio cholerae*
		Other (fomite) ingestion	*Shigella* spp.
	'Close contact'	Respiratory (airborne)	Influenza 2, RSV, *Bordetella pertussis*, MMR
		Oral–fecal	*V. cholerae*, rotavirus
		Physical (nonsexual)	HBV, HSV1, EBV
	Sexual	Genital–genital, anogenital, etc.	HIV, HBV, HSV2 *Neisseria gonorrhoeae*, *Treponema pallidum*
	Vector-borne	Vector-borne	*Plasmodium* spp., urban YFV, dengue
	Blood-borne	Needle sharing/transfusion	HBV, HIV, HCV
Zoonotic	Physical contact	Various	Rabies, Q-fever, brucellosis, *Campylobacter* spp.
	Vector-borne	Vector-borne	*Yersinia pestis*, jungle YFV, *Borrelia burgdorferi*
Environmental	Environment	Respiratory (airborne)	*Legionella* spp.
		Oral/Mechanical	*Clostridium tetani*, *Listeria* spp., *Mycobacterium bovis*

CMV, cytomegalovirus; EBV, Epstein–Barr virus; HAV, hepatitis A virus; HBV, hepatitis B virus; HCV, hepatitis C virus; HIV, human immunodeficiency virus; HSV, herpes simplex virus; MMR, measles, mumps, and rubella; RSV, respiratory syncytial virus; YFV, yellow fever virus.

and c_3 as the average number of different sexual partners per year. If the probability of a child becoming infected from its infectious mother is p_1, and similarly for p_2 and p_3, the total average rate of people infected by each infected woman is:

$$c_1p_1 + c_2p_2 + c_3p_3 \quad (7)$$

There is considerable blurring across boundaries in Table 1, as with any attempt to impose categories on to continuous scales, e.g. when does close contact, oral–fecal transmission become food-borne environmental contamination? One can see the difficulty in defining the nonsexual 'close contact' rates (although see Edmunds et al. 1997). This is also complicated by the fact that close contact modes and sexual modes are not mutually exclusive – if two individuals are close enough to touch, they can transmit via the respiratory mode. In this sense, the sexual route is a 'very close contact'. Figure 5 schematically demonstrates that, within the close contact/sexual routes, there is a relationship between the number of contacts and intimacy of contact (which is very probably correlated to probability of transmission). Thus, we speak to more people than we touch, and touch more people than we have sex with.

By defining a transmission mode as 'respiratory', we are defining the lower limit of its transmission modes, because it will also be transmitted during more intimate contacts. Figure 6 schematically illustrates that this lower limit will not always coincide with the maximum transmission route: how much influenza is sexually transmitted (that is, transmitted during sexual contact)?

Social and environmental setting

Having defined and quantified transmission in terms of contact rates, the next level of complexity is determining with whom the contact occurs. The simplest assumption is that all individuals within the population are equally likely to contact all other individuals. This is in fact the underlying rationale behind Equations 1–3, and the effect is that doubling the number of infectious individuals doubles the rate at which each (and every) susceptible contacts an infectious individual. In reality this is rarely the case – we do not have an equal chance of meeting everybody. Social systems effectively mean that we have a group of people we meet much more often (e.g. family, close friends, and work colleagues), and have a very low chance of meeting most other people.

There are a large number of variables that determine who our contacts are. These include age, gender, occupation, and geography. Taking age as an example, people tend to mix with individuals of the same age, although parents and teachers with children are examples of mixing across age groups. Geography is somewhat spurious, because it does determine much of the contact, but behavior tends to be overriding, so that it is possible to have more regular and closer contact with family members in North America, than with next-door neighbors in the UK.

There is also considerable heterogeneity in the amount of contact, so that some individuals have much higher contact rates than others. The individuals with the highest contact rates are simultaneously at greatest risk of becoming infected, and have the greatest opportunity for infecting others. In the context of STIs, these high-contact individuals are termed the 'core group', but all infections have a 'core group', and the same phenomenon is probably universal for infectious agents (Woolhouse et al. 1997).

In much work in the literature, there is an implicit assumption that the rate of infection is determined by the density (or size) of the population, rather than being

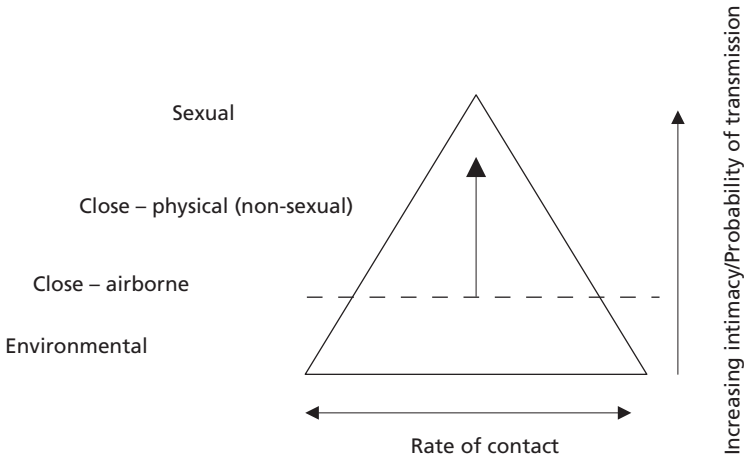

Figure 5 *Schematic diagram representing the relationship between the frequency and intimacy of contact. The higher up the triangle, the greater the probability of transmission, but the lower the rate of that contact. The horizontal line represents a hypothetical infection which is transmissible via direct airborne spread, but shows that it is also transmissible by other routes (see text).*

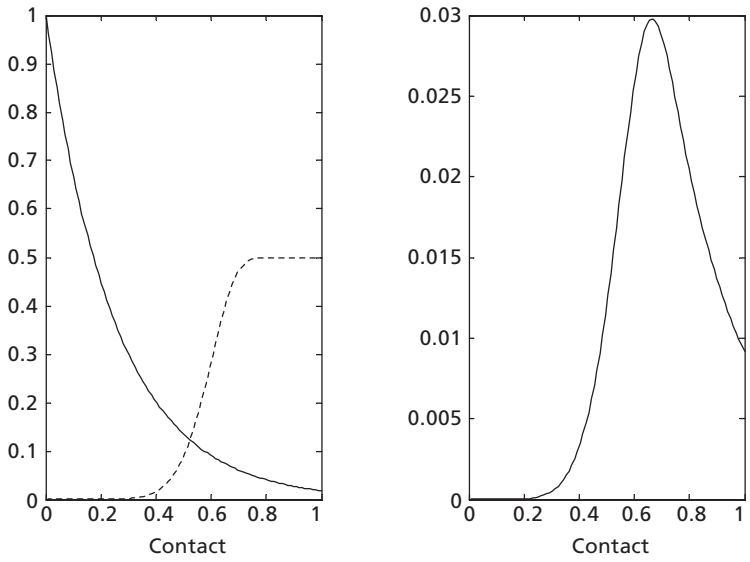

Figure 6 *Putative relationships between (relative) contact rate,* c *(solid line left panel), and probability of transmission,* p *(dashed line left panel), varying with increased intimacy of contact. The right-hand panel shows the product* c^*p *over the same scale, i.e. the effective contact rate. Note that if the contact rate falls and probability of transmission reaches a plateau, this latter relationship will always have a single maximum, and the maximum will be at or before the maximum transmission probability is reached.*

determined by contact explicitly. In this case, Equation 2 is rewritten as:

$$\beta Y \tag{8}$$

where β is a 'transmission coefficient'. This formulation is known as the 'mass action' assumption: the name derives from similar models (and assumptions) in chemical and physical processes. If the population size (N) is constant, the two assumptions (contact-driven and mass action – Equations 2 and 8, respectively) are equivalent, and the transmission coefficient subsumes the population size. If the population size is changing, the two are equivalent only if the contact rate is a linear function of the population size (i.e. if doubling the number of people doubles the average rate of contact). This might be a fair approximation for transmission via more environmental routes (such as airborne), but is unlikely to be true for more sociological routes (such as sexual contact).

It is clear that much of this discussion about social and environmental setting and its relationship to transmission rates depends on the population under consideration. For any model, defining the population is a critical step, because it effectively defines the scope of the model, which then determines what is outside the model, e.g. producing a model of pneumococcal transmission in school might be erroneous if most of the transmission occurs in households. The other important feature to come out of this discussion is that heterogeneities (i.e. differences) are critically important. The simplest model formulations have everything identical. In biology, this is very rarely the case – most hosts and most pathogens are distinct from each other. This theme is picked up continuously through the remainder of the chapter.

Natural history

For the purposes of describing transmission dynamics, the natural history of infection charts the progress of *an individual* through time, starting with exposure and successful infection. Within each infected individual, there is a dynamic duel fought between pathogen and immunity – vaccines are designed to give immunity the upper hand (Nowak and May 2000). But, at a population level, there are four characteristics of relevance: (1) the time course of infectiousness; (2) the immunity to subsequent infection (i.e. susceptibility); (3) the time course of immune markers of (past) infection; and (4) the time course of disease. Figure 7 shows schematic pictures of these four aspects for three diseases. Measles, mumps, and rubella are archetypal viral infections, where the infection, disease, and immune response to infection all occur over a matter of days. The infection (and infectiousness) is curtailed by the immune response that persists for life, and antibody markers of previous infection can be found in the serum and saliva of most individuals, although their concentration may fall over a period of years without re-exposure.

For bacterial infections (e.g. *N. gonorrhoea*, *Streptococcus pneumoniae*), the timescale of infection is months, there is no solid immunity, and immune markers are generally not persistent.

For hepatitis B virus (HBV), there are two possible outcomes of infection. After initial exposure, and a risk of acute hepatitis, the majority of individuals recover and become immune to re-infection, i.e. the natural history is as for measles, but with a timescale of months rather than days. However, as illustrated, some

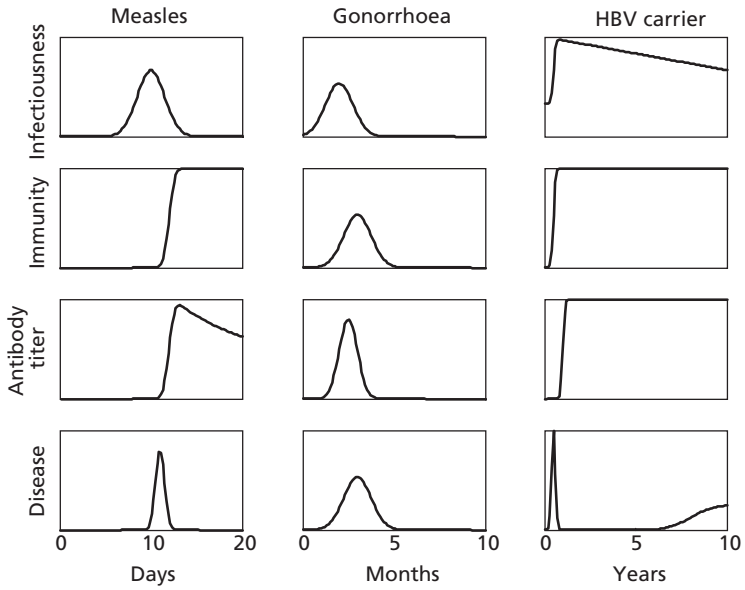

Figure 7 *Schematic representation of three different natural histories without intervention (treatment). The three columns show (left to right) measles, gonorrhea, and* hepatitis B virus *carriage. Note the different time scales (i.e. the time since infection). The four rows show (top to bottom) the infectiousness, the immunity to reinfection, the titer of antibodies (markers of previous infection), and the risk of disease and/or symptoms.*

individuals develop a carrier state, and remain more or less continually infectious, although they are probably immune to further infection, and maintain some antibody markers of infection. The risk of cancer and cirrhosis increases with duration of carriage.

To develop a mathematical description of the natural history, the most common (and common-sense) approach is to divide the population into a series of mutually exclusive categories or classes of individuals (as was done in Figure 3). Figure 8 illustrates such compartments for the three infections in Figure 7. The arrows denote the flow or movement of individuals between categories. For measles, there are only three states: susceptible, infectious, resistant (SIR), and individuals move from susceptible to infectious (when infected) and from infectious to immune as they recover. This is the classic 'SIR' model. Frequently, an exposed category is added between susceptible and infectious to include those individuals who are infected but not yet infectious: this is the SEIR model. For most bacterial infections there is no effective solid immunity, so individuals return to susceptible after resolution of infection:

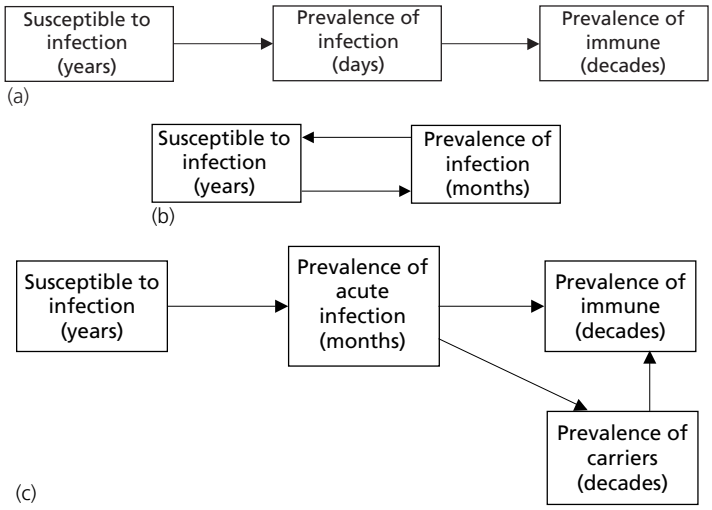

Figure 8 *Compartmental model structures for the natural histories of three infections illustrated in Figure 7.* **(a)** *Measles,* **(b)** *bacterial sexually transmitted disease, and* **(c)** hepatitis B virus*. The duration of stay within each compartment is written in braces. The first two model structures are SIR and SIS respectively.*

the SIS model. Again, if there is a period of immunity after infection, before recovery of susceptibility, an SIRS framework is possible, as seems likely for respiratory syncytial virus (RSV) and rotavirus. For HBV, the compartmental model should include both consequences of initial (acute) infection: immunity and carriage. Note that carriage can resolve, so that there is a flow from carriers to immune. Figure 8 is not exhaustive: indeed there are a great many possibilities for sewing together compartments representing the natural histories of different pathogens (which might be different in different host populations). But note that the compartments are based on what happens within individuals.

Figure 8 also shows the duration of stay within each compartment. This is important, because it largely determines the prevalence of each compartment, i.e. what percentage of individuals are in which state. A short duration stage has a lower prevalence than a long duration stage, e.g. the prevalence of people whose 40th birthday is today is much lower than the prevalence of people in their 40s: because it takes only one day to have a 40th birthday, but 10 years to move between 40 and 50.

As discussed below, for the purposes of understanding transmission, the duration of infectiousness (D) is the most important parameter of the natural history.

Pathogen heterogeneities

> Measles occupies a rather unique position in epidemiological theory, as it is largely an infection of childhood with very clear-cut immunizing characteristics, so that the susceptible population (and its new 'recruits') are fairly well defined. (Bartlett 1960, p. 73)

We can perhaps add mumps and rubella, but most other pathogens display variation, particularly with respect to immunity determinants. Agents with antigenic diversity (e.g. influenza virus, rhinoviruses, rotavirus) appear to have natural histories like the second type in Figures 7 and 8, i.e. every infection is like a new one. The typical scenario might be that of a strain of influenza, which follows a similar life history to that of, say, measles, but, unlike measles, the solid immunity generated to the specific strain is not solid across strains. Thus an individual's immunity to 'influenza' as a whole is compromised by the antigenic diversity (existing or immune selected), such that in a subsequent season previously infected individuals succumb to a new (drifted) variant. From a host viewpoint, this looks like loss of immunity to influenza. From the virus's viewpoint, all those hosts that were previously infected and immune are now susceptible and ripe for re-infection.

This picture is complicated by the concepts of partial and temporary immunity. If immunity is partial, it is effective against a proportion of the pathogen population, whereas, if it is temporary, it is effective against the whole pathogen population, but this immunity wanes. Further complication arises if the immunity is to disease rather than infection: for RSV and rotavirus disease is usually expressed or most severe on first infection.

Basic reproduction number

The processes outlined above (transmission, contact, and natural history) are the determinants of the epidemiology of an infectious disease in a given host population. That HBV has a different epidemiology in developed versus developing countries, or that STIs are different from childhood viral infections, is the result of differences in these three processes.

To understand the population dynamics of infection, we should capture the processes as they determine transmission from person to person. This can be done in terms of a single number: the basic reproduction number, R_0 (pronounced R-zero or R-nought). This turns out to be the central concept in infectious disease epidemiology.

Consider a completely susceptible population (i.e. without any immunity), with a single infected case introduced. In this situation, the transmission that derives from the infected case will be maximal – it is the ideal situation for the pathogen. The infected case will be infectious for a period determined by the natural history, and in the simplest circumstance we can represent this by the parameter D. This determines the time window or duration over which infection can occur.

During this period, the case will make contact with susceptible people at a rate c, which is determined by the transmission route and the population characteristics (environment and behavior). So, overall, the number of potential infectees (secondary cases) will be cD – the number of contacts during the infectious period. But not all will become infected, and we can write p as a transmission probability, i.e. given that a susceptible contacts an infectious person, p is the probability that transmission will occur. So the basic reproduction number can be defined as:

$$R_0 = pcD \tag{9}$$

Note that this is a single number and is defined as the average number of secondary cases that are derived from one primary case in a completely susceptible population. As previous discussion on heterogeneity in transmission and natural history illustrates, the word 'average' in this definition glosses over much complexity, but the concept conveys the essential idea that the maximal expected transmission in a given setting can be quantified in terms of route of transmission, environmental/behavioral setting, and natural history.

The most important concept resulting from R_0 is that of a threshold value for an epidemic to occur. If an infection is to be able to propagate through a population, i.e. to cause an epidemic, each new infection will have to (on average) infect at least one other person. So for an epidemic to occur:

$$R_0 > 1 \tag{10}$$

Imagine, if $R_0 = 2$, each infectious case will create a chain of new cases, so that one case becomes 2, which beget 4 cases, which beget 8 cases, and so forth.

Effective reproduction number

Given that susceptibility is the key quantity – the food on which infection feeds – there ought to be some way of determining a sufficient supply of susceptibles required to maintain infection. This idea is captured in the *effective reproduction number*, R. This is defined as the average number of secondary cases from each primary case. Note the similarity with the definition of the basic reproduction number, which differs only by having the extra condition of a completely susceptible population. The effective reproduction number does not have this condition – it is more general and applies regardless of the state of the population.

There is a simple relationship between these two reproduction numbers. The assumption previously was that each contact (potential transmission) that the infectious case had was with a susceptible person. However, if only a proportion of the population is susceptible, x, then the number of contacts each infectious case has during the infectious period is xcD, and consequently:

$$R = pxcD = xR_0 \tag{11}$$

When everybody is susceptible, $x = 1$, and $R = R_0$. If there are no susceptibles, $x = 0$, and $R = 0$, i.e. there can be no transmission.

Host population effects

Viruses survive in host populations, so, not surprisingly, the population dynamics of hosts is an important factor in determining the epidemiology of a virus. There are two aspects that we concentrate on here: the availability of susceptible hosts and the variability of the effect of infection on different hosts. A key concept is that hosts are not identical, and we emphasize the role of host age.

In Figure 4 the epidemic ends and the virus that caused it will become eliminated from the host population. This is because all (but a small fraction of) hosts have been infected and are immune, and there is no susceptibility available for the virus to exploit. Pathogens need susceptibility to survive. A pathogen with a different natural history, e.g. one with sufficient antigenic diversity, might be able to re-infect hosts, thus creating susceptibility. The other principal source of susceptibles is the arrival of new hosts through birth or immigration. An alternative strategy is for the pathogen to find a site in which it can survive the longer term and wait for susceptibility to return. A carrier state and survival in the environment are both examples of such strategies; vertical transmission is also a good adaptation for a virus to survive in a small population of hosts.

We can adapt the simplest model in Equations 4–6 to include a supply of susceptibles. Imagine that, in our population, individuals leave the population after 20 weeks on average, and they are immediately replaced by susceptibles, in order to keep the population constant. This can be thought of as birth/death or immigration/emigration, and is captured in a parameter, μ. We also include partial immunity by adding a parameter, π, which we define as the proportion of recovering hosts that are immediately susceptible (so that $1 - \pi$ become immune). The equations for this system are:

$$\frac{dX}{dt} = \mu N - pc\frac{Y}{N}X + \pi\frac{1}{D}Y - \mu X \tag{12}$$

$$\frac{dY}{dt} = +pc\frac{Y}{N}X - \frac{1}{D}Y - \mu Y \tag{13}$$

$$\frac{dZ}{dt} = (1-\pi)\frac{1}{D}Y - \mu Z \tag{14}$$

Four examples of the results are shown in Figure 9. Introduction of a trickle of susceptibility that does not depend on infection (through birth/death) results in the infection being maintained in the population – the supply of susceptibles is enough to keep all the chains of transmission from going extinct. Note that this introduces 'damped oscillations', as the infection reaches its endemic, equilibrium prevalence. Decreasing partial immunity increases the prevalence of infection and reduces the amplitude of the oscillations.

This model (Equations 12–14) is an example of a 'toy model' or 'thought experiment' in which the underlying effect of explicitly stated assumptions can be investigated. Nobody would pretend that a framework such as this be used for quantitative prediction or designing control programs. More complicated models, e.g. introducing explicit host age, gender, and pathogen diversity, would be required for these purposes. However, these more complex models tend to echo the important results from the simpler models, which are consequently often more useful for developing understanding. A fuller review of the dynamics of SIR and SIS models is given by Gomes et al. (2004).

Dynamic equilibria

Implicit in Figure 9 is that if there are sufficient susceptibles to maintain an infection in a host population, i.e. it becomes endemic; then the prevalence of infection tends toward a constant equilibrium. This can

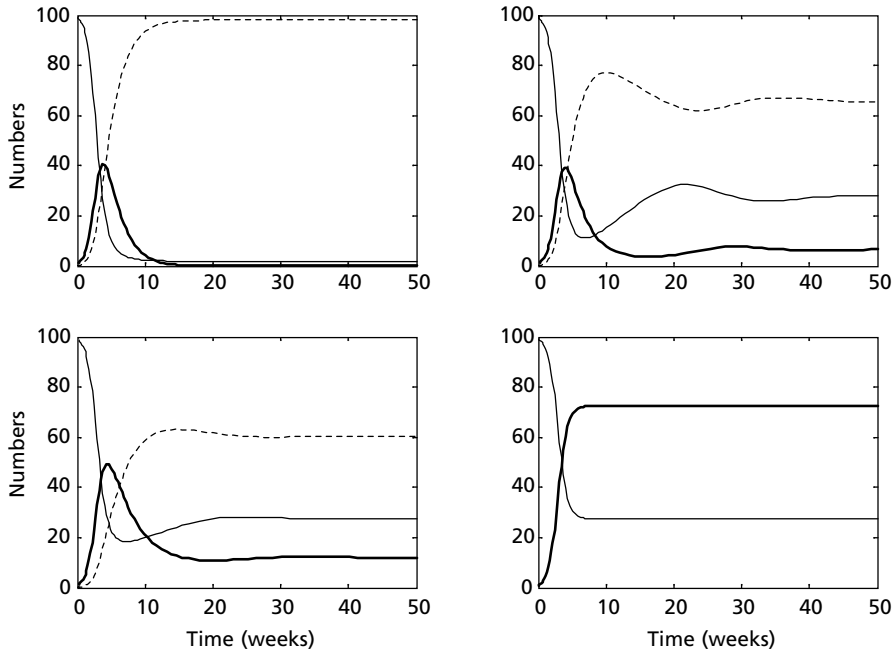

Figure 9 *The effect of supplying susceptibles on epidemic propagation (see text and Equations 12–14). The first panel shows the epidemic with no susceptible supply (SIR – as Figure 4). The second panel introduces birth/death (with $\mu = 0.05$ so that each individual has an expectancy of staying 20 weeks in the population). The third panel introduces partial immunity ($\mu = 0.05$, $\pi = 0.5$). The fourth panel shows the SIS situation, with no immunity ($\mu = 0.05$, $\pi = 1.0$). The remaining parameters are as Figure 4.*

be related back to the effective reproduction number. At endemicity, on average, each case will give rise to one other case, i.e. $R = 1$, and prevalence is constant.

This equilibrium is also dynamically stable. Figure 10 shows the situation where additional susceptibles are either added or removed from a population at endemic equilibrium. The removal of susceptibles (e.g. by a one-time vaccination campaign – left column in Figure 10) results in a decrease in transmission ($R < 1$) and consequently the number of infectious individuals. Susceptibles entering the population are less likely to get infected than at equilibrium, so their prevalence rises, as does R. When $R = 1$ the number of infectious individuals bottoms out, and starts to rise as the numbers of susceptibles increases and $R > 1$. A small epidemic ensues. The addition of susceptibles (right column in Figure 10) immediately results in an epidemic ($R > 1$) during which the additional susceptibles are 'consumed'. In both cases susceptibility and infection return to equilibrium where $R = 1$.

The value $R = 1$ is a special situation, and decreasing or increasing the proportion susceptible moves R away from this value, although infection dynamics will act to increase or decrease the proportion susceptible and bring R = 1. The value $R = 1$ occurs when the proportion susceptible is at a *critical value*:

$$x^* = \frac{1}{R_0} \qquad (15)$$

Transmission dynamics acts to keep the proportion susceptible at this critical value.

BASIC PRINCIPLES OF VACCINATION

Having discussed some of the basic concepts and potential complexities, we turn, at last, to the effects of vaccination. For each individual host, successful vaccination is a short cut in the natural history that results in moving from susceptible to immune without the infection. For the pathogen, vaccination means removing susceptibility, i.e. potential hosts. As we have seen, susceptibility is a key quantity in determining the population level dynamics of infection, so vaccination will have dynamic consequences. In particular, because individuals are not independent, vaccinating some hosts will have consequences for those hosts who are not vaccinated.

Herd immunity and reproduction numbers

An important concept in infectious disease is that of herd immunity, which is often confused so we adopt a particular definition. A population (herd) can be said to be immune to a specific pathogen when that infection is not endemic and cannot be introduced. In particular, the in-migration of infected people will not result in continuous chains of transmission and an epidemic. A more poetic term is 'community immunity'.

For an epidemic to occur, and consequently the infection has the potential to become endemic, the effective reproduction number must be greater than one. In a

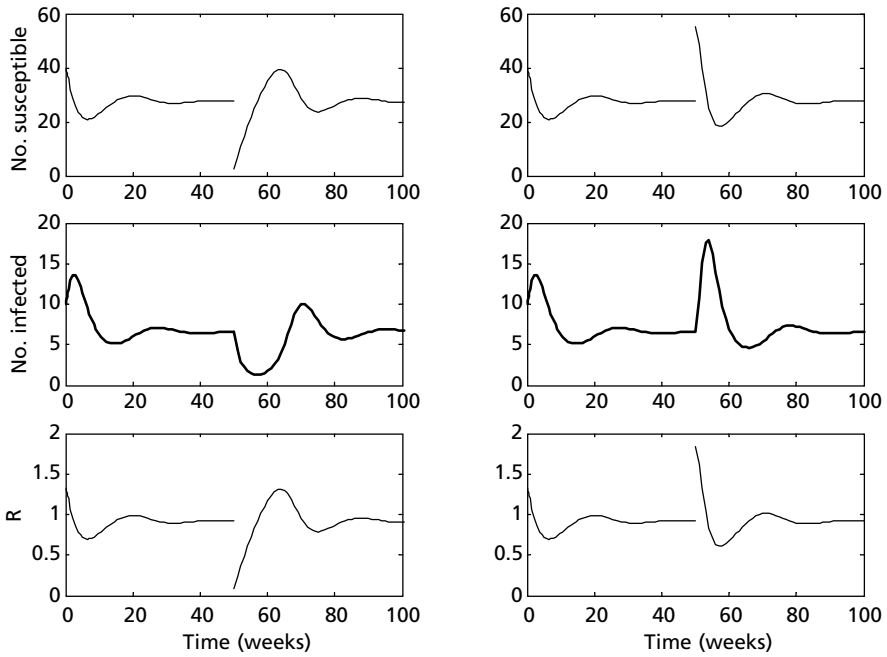

Figure 10 *Dynamic effect of increasing or decreasing the proportion susceptible at one point in time. The model (Equations 12–14); $\mu = 0.05$, $\pi = 0.0$) is run for 50 weeks, then either 90 percent of susceptibles are moved to immune class (left panels) or the number of susceptibles is doubled by movement from the immune class (right panels). The rows show the effect on susceptible class (top row), infected class (middle) and effective reproduction number (bottom) (immune population not shown). Note that susceptible numbers and effective reproduction numbers are linear transformations of each other (Equation 11).*

completely susceptible population, the basic and effective reproduction numbers are equal, but reduction in susceptibility directly (and linearly) reduces the effective reproduction number (R_0 remains unchanged by susceptibility). Without any natural infection in the population, we can divide the population into two categories: the proportion susceptible, x, and the proportion who have been successfully made immune to infection through vaccination, p_v. Figure 11 shows the relationships between these quantities. If the proportion susceptible is forced below its critical value, x^*, by immunization, there are insufficient susceptibles to permit an epidemic. The proportion of the population that must be immunized to achieve this is:

$$p_v^* = 1 - x^* = 1 - \frac{1}{R_0} \qquad (16)$$

Thus, if $R_0 = 2$ then $p_v{}^* = 0.5$ so that immunizing more than 50 percent of the population will mean that, if the infection is introduced, $R < 1$ and an epidemic will not occur.

The tantalizing upshot is that a population is immune to an epidemic even though a proportion of the individuals remains susceptible. The unvaccinated individuals derive their protection from the vaccinated. Vaccination of individuals not only protects them directly, but also protects the unvaccinated. Much of the theory of immunization is about working out how large the proportion susceptible can be without leaving the community vulnerable to pathogen invasion.

Vaccination and susceptibility

In the previous section, we considered the introduction of a pathogen *after* the introduction of vaccination. However, the more usual situation is introduction of the vaccine into a population in which the pathogen is already endemic.

The fundamental concept is that, while an infection remains endemic within a population, vaccination does not reduce the proportion susceptible in the population. Instead it replaces those with a previous history of infection (and now immune) with those vaccinated. This is illustrated in Figure 12, using the simple model of Equations 12–14, but allowing a proportion, v, of births to enter the immune class directly (i.e. they are vaccinated before any exposure). As susceptible individuals are removed by vaccination into the immune class, the proportion susceptible *temporarily* declines. The dynamic effect is very similar to that shown in Figure 10. Eventually, for a given vaccination rate (which does not eliminate the infection, $v < 0.7$) there is a balance achieved between input to the susceptible pool (from births) and output from the susceptible pool, which is now divided up by the processes of infection *and* vaccination. The upshot is that the proportion susceptible regains its pre-vaccine level, but not so the proportion infected, because removal of susceptibles is now a process shared between infection and immunization.

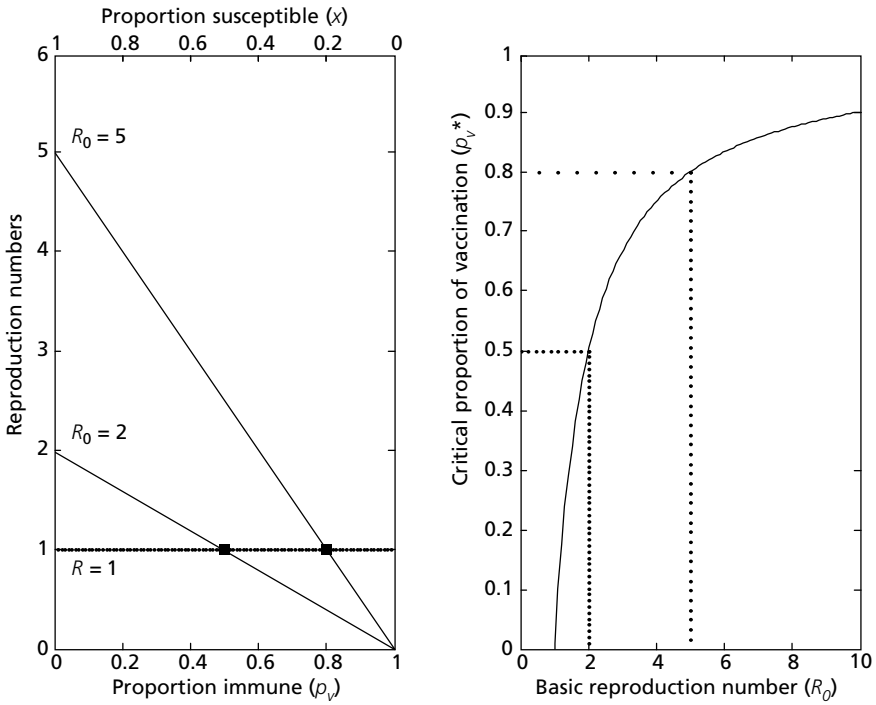

Figure 11 *Community immunity: the relationships between the proportion vaccinated,* p *, the proportion susceptible,* x*, and the reproduction numbers,* R_0 *and* R*. The left panel gives two examples, for* $R_0 = 5$ *and* $R_0 = 2$*. As the proportion immunized increases, so the effective reproduction number (solid lines) in each case decreases linearly. The critical value, i.e.* R *= 1, is marked. The right panel shows the relationship between the basic reproduction number and the immunization proportion required for* R *= 1. The two examples (*$R_0 = 5$ *and* $R_0 = 2$*) are marked as dotted lines.*

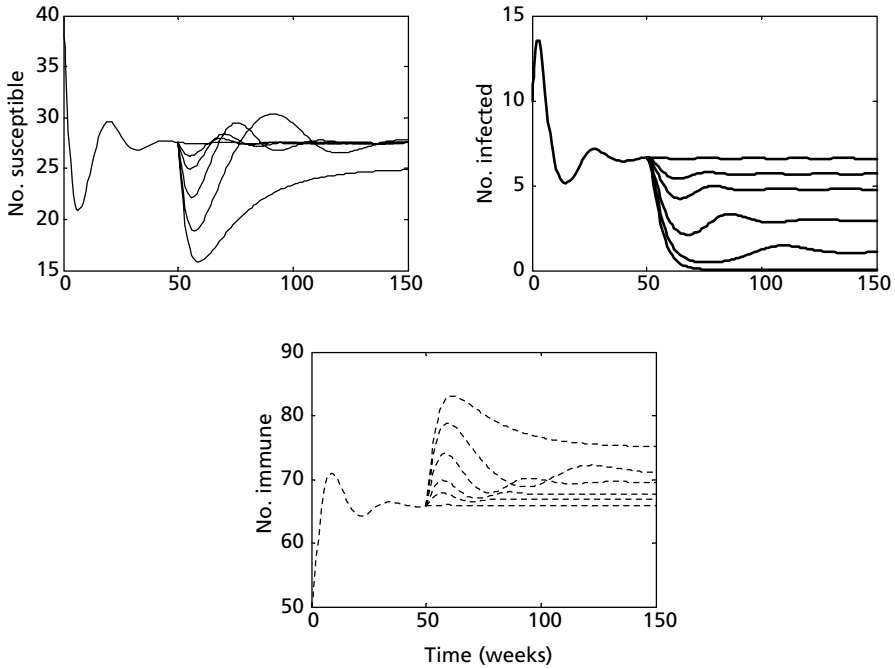

Figure 12 *Illustration of the dynamic effects of immunization using the model defined in Equations 12–14, modified to include vaccination at birth (see text). The panels show the numbers of susceptible, infected, and immune respectively. The model is run to equilibrium for 50 weeks, and immunization introduced at six levels (*v *= 0, 0.1, 0.2, 0.4, 0.6, and 0.75 where* v *= 0 is no vaccination). Here* $R_0 = 3.33$ *and* $p_v^* = 0.7$*.*

Only when immunization forces the proportion susceptible below the critical proportion, x^*, does the pathogen become extinct. For this example, when $v = 0.75$, which is greater than 0.7, there are not sufficient susceptibles entering the population for $R = 1$ to be maintained. In this case the infection becomes extinct, but a proportion of the population (25 percent) remains susceptible and 75 percent are immune. Note that the threshold required to eliminate infection from a population is the same as that required to protect a population from invasion (i.e. herd immunity). Again, it is not necessary to immunize all the members of a population to eliminate the infection.

Time (dynamic) effects of vaccination

Following the introduction of a vaccine, given a high enough coverage to appreciably reduce the proportion susceptible, cases of infection will decrease, often markedly so. This is particularly the case with infections that have short latent and infectious periods. A period of low incidence occurs, which is frequently ended by an alarming rebound in cases. This rebound, after what has been termed a 'honeymoon period' (McLean 1992), arises because of a rebound in the proportion susceptible well above the epidemic threshold, while incidence is low (see above and Figure 10). The rebound is an expected epidemiological consequence of vaccination and not a failure of vaccination policy as such, although they are frequently ascribed to a failure in vaccine or vaccine delivery. In the longer term, although vaccination coverage remains below that required for elimination, epidemics are likely to continue but less frequently than was the case before vaccination. This is because after each epidemic the rate of replenishment of the susceptible pool to epidemic proportions is reduced compared with pre-vaccination in proportion to level of vaccine coverage.

In general the impact of vaccination programs may not be immediate, because the targeting of single age classes generates only a gradually increasing proportion of the population with vaccine-induced immunity. The extreme of this would be a program of universal infant vaccination for an infection transmitted by sexual contact, such that a lag of a decade would arise before those protected by vaccination aged into the at-risk sexually active groups. In response to this it is now common to introduce routine immunization procedures with an initial one-off catch-up program of vaccination to a wide segment of the risk population.

Age effects of vaccination

Given that vaccination will tend to result in a reduction in the proportion infected, and hence lower the force of infection (see above and Figures 10 and 12), the average time for an individual, following birth, to be exposed and infected will increase. Thus the average age at infection will increase as a result of vaccination. The relationship between the transmission potential of an infection (R_0), the proportion vaccinated, v, and the long-term (equilibrium) average age at infection, A_v, is:

$$A_v = \frac{L}{R_0(1-v)} \qquad (17)$$

where L is the life expectancy at birth. This is shown in Figure 13 for an archetypal virus (also assuming one survival type where all individuals born live until the average life expectancy from birth). Clearly, the effect on A_v is greater for higher levels of coverage, for less transmissible infections (lower R_0), the younger the age at delivery (i.e. where the proportion susceptible is higher), and for nonselective rather than selective vaccination.

The implications of increasing the average age at infection are various (Nokes and Anderson 1988; Anderson and May 1991), dependent, for example, on the age-related nature of disease caused by infection (see also Coleman et al. 2001). Where, like measles, the risk of mortality declines with age, a rise in age at infection in those who missed vaccination will translate into an additional indirect benefit of the vaccine program.

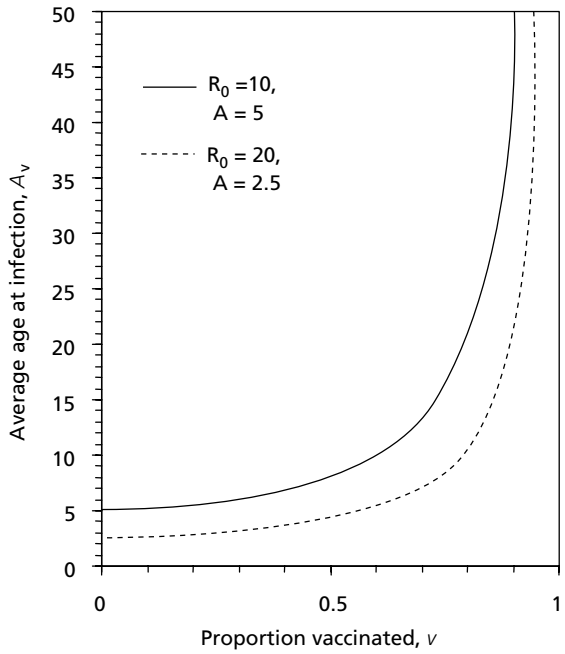

Figure 13 *Vaccination increases the average age at infection. The relationship between the proportion vaccinated at birth, v, and the new average age at infection under such vaccination pressure, A_v, is shown for two infections with different reproductive capacities. Where the value of R_0 (20) is highest, and thus the average age at infection, A, in the absence of vaccination is lowest, the impact of a specific level of vaccine coverage on A_v is, in absolute terms, less than for the infection with lower R_0 (higher A) – although the proportional change is equal. (Adapted from McLean 1992.)*

This would also apply to HBV infection and the risk of developing long-term carriage (Medley et al. 2001). In contrast, where the risk of disease increases appreciably with age, e.g. the risk of intrauterine infection from rubella which increases nonlinearly in relation to fertility, the beneficial effect of a particular vaccine program in reducing cases of infection may be severely undermined by the increased risk of severe disease arising from those cases that remain and occur at an older age (Anderson and Grenfell 1986). Observational evidence that supports this theoretical prediction was a recent epidemic of rubella among women of childbearing age in Greece (Panagiotopoulos et al. 1999).

In parallel with the increase in average age at infection resulting from vaccination, the average age of the proportion susceptible will increase (Nokes and Anderson 1988). Again, this is supported by data (Ukkonen and Von Bonsdorf 1988; Ukkonen 1996; Bahri et al. 2003). As different age groups show differing behavior, e.g. mixing patterns, changes in the age distribution of susceptibles may appreciably alter the observed epidemiology of the infection where the behavior in question is related to the route of transmission. For example, studies demonstrate that the susceptible risk of exposure to a variety of viral infections (e.g. MMR, HBV, pertussis) changes with age, presumably because of age-related changes in mixing, and other behavioral characteristics (Anderson and May 1985; Nokes et al. 1986; Edmunds et al. 1997). A general trend appears to be for a decrease in the force of infection with increasing age. Thus, vaccination tends to move susceptibles into older age groups where they are both less likely to acquire infection and less likely to transmit it. One outcome of this phenomenon is that the predicted vaccination coverage for herd immunity is diminished.

Vaccine characteristics

Vaccines are usually imperfect. The immunogenic and reactogenic characteristics of vaccines are central to predictions of their impact at a population level. Most successful vaccines have been developed against infectious agents possessing a single serotype, i.e. all variants are antigenically similar, and the host immune system sees them as the same entity with equal variant specific to variant cross-immunity. The immunogenic properties have been classified into three parameters: take, degree, and duration (Halloran et al. 1992; McLean and Blower 1993): 'take' is the proportion of vaccinated individuals who produce an immunological response to the vaccine; 'degree' is the degree of protection provided by the immunological response generated by the vaccine; and 'duration' is the time span of the immunological response.

These three attributes capture both variability between individuals (take) and the average response within those individuals that respond (degree and duration). The efficacy of a vaccine is the combined effect of a vaccine within an individual (and is a combination of all three characteristics). The effectiveness of a vaccine is a measure of the combined effect of a vaccine within a population. The effectiveness thus includes the results of herd immunity, and includes the protection given to the nonvaccinated individuals.

Delivering the vaccine

Mechanisms for delivering vaccine to the target population vary considerably. The reasons for these differences arise from (1) the need to target individuals most at risk, e.g. *Haemophilus influenzae* in infants versus hepatitis B in drug-using adults; (2) existence of mechanisms by which to deliver vaccines efficiently, e.g. maternal–child health services or general practice clinics; and (3) different transmission routes.

From the perspective of representing the delivery mechanisms accurately in models, the key characteristics are (1) age at delivery, (2) proportion receiving vaccine, (3) vaccine failure rate, and (4) selectivity of vaccination based on past disease, risk group, or vaccine history. Model structures may need to alter to reflect the particular mechanisms of delivery, e.g. universal infant vaccination might be modeled most simply as the redirection of a proportion (v) of all individuals born into the population into a vaccine-immunized class whereas the remainder ($1 - v$) enter other population classes – usually the susceptible class (see Figure 12). This assumes 0 percent primary vaccine failure, no influence of maternal-derived specific antibody, and random delivery of vaccine, i.e. no overt selection procedure for vaccination. However, this simple model might not adequately describe the situation if the vaccine is neutralized by the presence of maternal antibody (e.g. live attenuated vaccines), or must be delivered across a range of age classes as in campaign or catch-up programs. In these instances, it will be more appropriate to consider age classes within the model structure.

The assumption of random delivery is implicit within most models, and in the estimation of summary parameters such as the herd immunity threshold. The basic assumption is that all susceptibles are equal, insofar as prevention of infection in any individual will prevent an equal number of future infections that would have arisen had that individual not been vaccinated. However, not all individuals are equal with respect to transmission: certain age groups may have higher rates of contact within their own and with other age groups (e.g. important in transmission of aerosol-transmitted infection); core groups exist in relation to the transmission of infections by sexual contact; super-spreaders have been suspected in recent severe acute respiratory syndrome (SARS) outbreaks in east Asia (Riley et al. 2003). So, targeting such groups with vaccine has a

disproportionately large, indirect, protective effect at the community level. In a different way, the control of smallpox through targeted vaccination of contacts to suspected cases illustrates a nonrandom delivery mechanism. In either case, the level of effective coverage required to develop herd immunity will be significantly less than that predicted through random delivery of vaccination, provided, of course, that the identification of 'super-spreaders' or contacts is accurate.

From an economic perspective, selectivity in delivery of vaccine may have cost–benefit implications, e.g. the benefits of selectively targeting highest risk groups (such as individuals attending STI clinics receiving HBV vaccine), with reduced numbers of vaccines delivered, may be outweighed by the costs associated with delivering the vaccine, which might involve prior screening for susceptibility and counseling (Williams et al. 1996).

Vaccination by repeated campaigns

The usual notion of a vaccination program is to vaccinate individuals as they pass some age gateway, e.g. infant vaccination schedules for diphtheria/tetanus/polio (DTP), HBV, *Haemophilus influenzae* b (Hib). However, vaccination across an age segment of a population has gained prominence in the last two decades either as one-off campaigns for the prevention of suspected epidemics or for 'catch-up' purposes, or repeated campaigns or pulses of vaccine aimed toward elimination. The idea is not new, and indeed, in the late 1950s, modeling studies of measles campaign interventions helped select the time interval between measles campaigns in west Africa, and led to temporary elimination of measles circulation for 3 years. More recently, repeated national vaccination days through social mobilization significantly contributed to the success in Latin America and the Caribbean in controlling measles and polio in the early to mid-1990s. This strategy has subsequently been extended globally for polio with remarkable success, and increasingly is part of accelerated measles control programs.

The principle underlying the idea of pulse vaccination is the targeting and removal of a large proportion of susceptible individuals in a short space of time through vaccination, thus suppressing the proportion susceptible below the threshold required to maintain chains of transmission, i.e. $R < 1$. This leads to a rapid decline in incident cases, particularly if the infectious agent in question has a short infectious period. If this process is repeated at a frequency that prevents the susceptible proportion ever rising to epidemic proportions, inevitably the infection must be eliminated.

This principle is schematically presented in the Figure 14. Based on this understanding it is possible to establish some simple expressions characterizing the frequency of campaigns given a particular level of campaign vaccine coverage. At its simplest, if a proportion v' of the population (i.e. of susceptibles if applied at random) is effectively vaccinated in a single pulse, then the time taken until the effective reproductive number attains unity ($R = 1$), is the pulse interval, given by:

$$T_v = \frac{v' x^*}{f} = v' A \qquad (18)$$

where f is the proportion of the population born each unit of time (e.g. year) and A is the average age at infection (before vaccination) (Nokes and Swinton 1997). Furthermore, if routine universal immunization (at

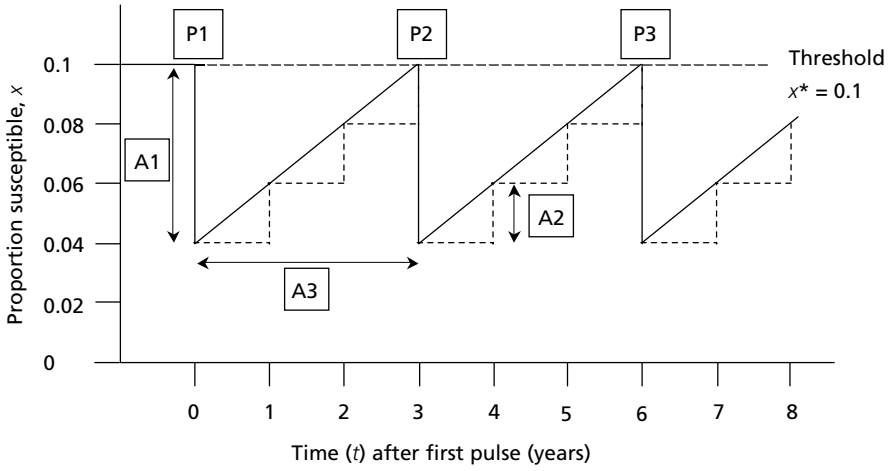

Figure 14 *Principle of pulse vaccination. A proportion, v′ = 0.6 (i.e. 60 percent) of all individuals are vaccinated in pulses P1–P3 at times 0, 3, 6, . . . et seq., when the proportion of the population susceptible is at its epidemic threshold (i.e. x = x* = 0.1 or 10 percent, arrow A1). Thus the proportion susceptible is reduced by 6 percent (i.e. v′x* = 0.06). Subsequent to each pulse, susceptibles increase at a maximum rate of f = 0.02 per year (A2) as a result of births (i.e. 2 percent of the population are born – and die – each year), assuming no continued infection (which would otherwise reduce the rate of replenishment of susceptibles). Thus, in 3 years (A3) the deficit in susceptibles caused by the vaccine pulse has been recruited by births, regaining epidemic proportion (x = x*) whence a further pulse is due. (Taken from Nokes and Swinton 1997.)*

around birth) is in place, at an effective coverage of v, then this slows the rate of replenishment of the susceptible pool, and extends the pulse interval:

$$T_v = \frac{v'A}{1-v} \tag{19}$$

Thus we obtain some general concepts about what is important in determining the program requirements for control through pulse vaccination, namely epidemiology and demography (i.e. x^* and f, which define A) and programmatics (i.e. v' and v). So that, given two infections that differ in their transmissibility such that one has a lower average age at infection than the other, then, within the same demographic context, control of infection 1 will either require more frequent pulses, or higher level campaign coverage, than infection 2. This is of some practical value in informing policy makers. In particular, the timing of pulses should be determined by the infection.

More generally vaccination is applied to specific age groups, e.g. under 5 year olds, where it is assumed most susceptibles are, and thus vaccine (which is usually delivered irrespective of past history of disease or vaccination) will be most efficiently used. Consequently, if effective vaccine coverage is not 100 percent, susceptible individuals may accumulate in older age groups, beyond the reach of childhood vaccination, which may alter the predictions of when subsequent pulses are required. This strategy may also accumulate numbers of at-risk individuals, e.g. women of childbearing age susceptible to rubella.

Again, this model deals with the issues very simplistically. More useful models for predictive purposes require explicit descriptions of these features, i.e. age structure, age-related mixing rates, accurate demographic schedules (Nokes and Swinton 1997). Such models thus become more specific to particular locations and setting and less general, i.e. they lose the quality of general insights to be gained from the 'too simple' models.

MODEL APPLICATION

In this section, we discuss some examples where models have been used to address specific problems. There are many types of model, some of which we have referenced here: none of them is 'right' in the sense that it captures reality; many of them will be 'useful' in the sense that they provide insight, understanding, and some quantitative predictions.

The question remains, for the non-modeler, of how to judge the quality of a model. There are two aspects. First, the assumptions used to design the model should be clearly and explicitly stated. You, the reader, should decide what processes you think are important (e.g. host age and gender) and determine if they are included. To simplify, models usually have to 'average' over heterogeneities, e.g. if the modeler does not believe that host gender has any effect, the model will have 'people' as its fundamental unit, implicitly taking an average of male and female. If there are significant differences between genders, the average will not be sensible and the model results are less likely to be useful.

Second, and more difficult for the nonspecialist, is that the model defined should be analyzed and solved properly. The best advice is to treat the model as any other technical, laboratory procedure. In that case you will be looking for some demonstration that the results are reliable, and that, in defined and known circumstances, the model produces the expected results.

Design of vaccination programmes: MMR

Rubella occupies a unique position in viral infections. A solid, life-long immunity develops after either infection or vaccination, and the disease caused by infection is solely related to infection during pregnancy. The objective of a vaccination program is clear – to reduce the incidence of congenital rubella syndrome (CRS). Given the relative simplicity, there have been several models developed that address this problem (e.g. Anderson and May 1983; Anderson and Grenfell 1986; Massad et al. 1994, 1995; van der Heijden et al. 1998; Edmunds et al. 2000).
